All the psychology associations of the Czech Republic are collective members of the Czech–Moravian Psychological Society, associated with the Academy of Science. The society has about 1700 individual members, representing about one-third of the total number of psychologists in the Czech Republic. The total number of psychologists in the Czech Republic is about 5500. Of the six associations, one is called Association of Clinical Psychologists of Bohemia, Moravia, and Silesia. Psychology is becoming more and more important within the healthcare system. Health services, including mental health services, continue to be available free of charge. In the area of counseling, privatization of services is progressing slowly. In the late 1990s only 25% of the counselors in the field of marital and family counseling have a permit for private practice.

2.29.3.3 France

La Société Française de Psychologie (The French Psychological Society) was founded in 1901 as a scientific society. It was only in December 1991 that practitioners were allowed to join the society, and in 1993 there were approximately 2000 members.

Psychology can be studied at 29 public universities and two private universities in France. The program takes five years and is subdivided in three parts. The first part takes two years and results in a *Diplôme d'Études Universitaires Générales* (DEUG). The second part, which also takes two years, results in a *Licence* or a *Maîtrice*. The third part takes one year and leads to the *Diplôme d'Études Supérieures Spécialsées* (DESS) in Psychology and *Diplôme d'Études Approfondies* (DEA) in Psychology.

The three main fields of practice are clinical psychology, work and organizational psychology, and educational psychology and guidance. The three main fields include many other fields such as psychotherapy, childhood and adolescent psychology, expert evaluation, neuropsychology, social psychology, cognitive psychology, economical psychology, and sport psychology.

Since 1985 the title *psychologue* has been protected by law on a national level enacted by parliament and government.

In 1991 Reyns and Verquerre published a study carried out in 1987. They mailed a questionnaire to all psychologists who obtained their DESS or DEA in 1984–1986. Only 895 psychologists (39%) responded. Of these, 659 (73.6%) were clinical psychologists, 151 (16.9%) were social psychologists, work psychologists, or organizational psychologists, and 85 (9.5%) were research psychologists. The major employers of clinical psychologists are national associations (e.g., Red Cross) (44%), the public sector such as child guidance centers (30.2%), hospitals (19.7%), and private practice (14.3%). The activities of the clinical psychologists were 58% clinical psychology, 32.7% institutional work, 31.1% psychotherapy, 26.9% training, 15.6% selection, and only 5.3% research (because many psychologists were involved with more than one activity this adds up to more than 100%).

Of the interviewed clinical psychologists, the following techniques were used: 59.8% used tests, projective techniques, or graphology; 88.3% used interview techniques; 42.9% used group interviews or group conferences; 5.1% used questionnaires or experiments; 22% used specific therapeutic techniques like psychoanalysis, gestalt therapy, or system therapy; 6.4% used a specific theoretical approach like psychoanalysis or system theory; and 3.5% used role-play techniques or transactional analysis. Of the interviewed clinical psychologists, 23.3% were unemployed, 67.4% had a regular monthly income, and 9.3% had a private practice. This relatively low percentage of clinical psychologists in private practice is due to the fact that there are no regulations in France. The independent clinical psychologist does not get paid by the government or a health insurance system. Because the French consider clinical psychology as a medical activity, and because they are not used to paying for medical activities themselves, it is almost impossible to run a private practice in France.

2.29.3.3.1 Postgraduate training

According to Reyns and Verquerre (1991), 57.5% of clinical psychologists follows some kind of postgraduate training. Approximately 20% of clinical psychologists have a secondary diploma from the third part. Apart from the university program there are many specialty training programs which are mainly complementary. There are programs in psychotherapy, psychoanalysis, psychopedagogics, criminology, sexuality, even graphology. There is an ethical code (*deontologie*) for the members of the *Société Française de la Psychologie*.

Payment is insured either by the state or by the *départments*. The psychological services that are covered by this system are health service (clinical psychology and psychotherapy), *départment* services (clinical psychology, psychotherapy), justice (clinical psychology, psychotherapy, expert evaluation), education (educational psychology, guidance), and private services (clinical psychology, educational psychology, psychotherapy, sometimes organizational psychology).

2.29.3.4 Germany

When looking at the situation of clinical psychology in Germany, one should bear in mind the fact that the reunification between East and West Germany only took place in 1990. The current *Berufsverband Deutscher Psychologen*, BDP (German Association of Professional Psychologists) includes members of the former *Gesellschaft für Psychologie der DDR* (Society of Psychology of the GDR). This information is based upon a representative survey of members of the BDP in 1990/1991 and former members of the GDR in 1991/1992. Of the 10 000 members of the BDP, one-third received a detailed questionnaire and 53.8% responded ($N=1630$), and of the 2500 members of the GDR, one-sixth received a detailed, and for the former East Germany, adapted questionnaire and 37.9% responded ($N=154$). This study was done by Schorr (1995). If we look at the subject sample we do not see any differences with regard to age (all are about an average of 43/44 years of age). However, there is a striking gender difference. Results showed that in the former West Germany the male–female distribution among psychologists was more or less fifty/fifty, in the former East Germany almost 70% were female. Another striking difference was the fact that at the time of the survey no psychologist was in private practice in the former East Germany compared with 27% in the former West Germany.

By comparing the areas of specialization one can see that clinical psychology was the largest specialization in what were West (81.5%) and East (70.9%) Germany. This was followed by work and organizational psychology in the West (11.2%) with only 7.1% in the East; while in the former East Germany, school and educational psychology came second with 16.2% with only 4% in the West.

By comparing the applied fields with each other it was first noticed, as was mentioned before, that 27.1% of the former West German psychologists worked in a private practice, whereas there were none in private practice from the former East Germany. Employment in counseling centers was about the same (18.9% in the former West Germany and 17.8% in the former East Germany). In clinics and rehabilitation clinics, one could see a significantly higher percentage of psychologists in the former East Germany (33.4%) contrary to only 14.3% in the former West Germany. In psychiatry the same kind of significant difference could be seen with 19.1% in the former East Germany and 9.7% in the former West Germany. For alcohol and drug therapy centers, the distribution was 4.6% in the former West Germany and 2.8% in the former East Germany.

If we look at the main tasks of a psychologist it can be seen that what were West and East German psychologists mention counseling and psychotherapy first (respectively 84.6% and 88.3%) followed by psychological assessment which was significantly higher for the former East German psychologists (West 51.1% and East 66.9%) and administrative duties which were significantly higher for psychologists from the former West Germany (West 32% and East 10.4%).

In summary, the above shows that the vast majority of psychologists in the former West and East Germany specialized in clinical psychology and that in the former East Germany about 55.3% of the psychologists were employed within a clinical setting, while in the former West Germany only 28.6% were working in a clinical setting. To what extent the percentage of psychologists in private practice are involved in clinical work remains unclear from this data.

2.29.3.4.1 Aspects of psychological training

(i) Basic training

In Germany there are 37 psychology programs at 36 universities. Each year approximately 6000 students apply to study psychology but only 3300 are accepted. In 1996 there were about 40 000 psychologists; around 6000 unemployed, 41% work in a clinical setting and 19% work independently as therapists or counselors. The whole study program takes six to seven years.

The *Hochschulramengesetz* (new frame law) regulates the general program of 10 semesters, without any specialization. However, many universities have not yet implemented this program. The idea is to add a third stage of around three years to the program, allowing about 5–20% of the *Diplom* students to continue to become "clinical psychologists." The consequence might be depreciation of the *Diplom* and an increase in unemployment which already is 20% for psychologists. This amounts to about 6000 psychologists between the age of 25 and 35 years, of which 60% are women. To date, the title "psychologist" is not protected by law. However, there is a *Berufsordnung für Psychologen* (ethical code) for members of the BDP.

(ii) Postgraduate training and supervision

Psychologists possess, to a surprising extent, further qualifications in addition to their degree in psychology. When quoting only academic qualifications as an example, 25.3% of the former West German psychologists and 10.4% of the former East German psychologists possess an additional qualification. When asked about postgraduate qualifications, qualifications in psychotherapy predominate. More than half of all German psychologists possessed a postgraduate qualification at the time of inquiry. Close to two-thirds of all German psychologists stated that they attended professional training regularly.

Because many psychologists possess a postgraduate training in psychotherapy, they tend to work curatively (not only advising as a counselor). This leads to a conflict of interest with physicians who in the strict sense of the word "curative" were the only ones allowed by the law of 1939 (*Heilpraktiker-Gesetz*) to practice a curative profession. Others are allowed to work in a curative way, however, they do not get paid by the health insurances directly. Psychologists only get paid if their service is requested by a physician. Since physicians are having problems in the job market themselves, they have started practicing psychotherapy themselves, and by doing so, have pushed psychologists out of the market.

In the late 1990s, there are close to 40 000 psychologists in Germany, increasing every year by around 1500. Of those, 41% are working in the clinicial area and 19% work independently as therapists or counselors. This means that only 60% of the psychologists who are trained in clinical psychology find a job in the clinical field. About 20% are unemployed, amounting to about 6000 psychologists between the age of 25 and 35 years old of which 60% is female. Of the 40 000 psychologists only 35% are members of the German Association of Professional Psychologists.

2.29.3.5 Greece

According to James Georgas (1995), when thinking about the history of psychology we should realize that twenty five centuries ago, the ancient Greek philosophers defined and explored the subject, making them the precursors of many theories of modern psychology.

For instance, the concept of empirism led to a school of behaviorism that has dominated psychology in the twentieth century. This concept was originally developed by Protagora, Empéricos, the Stoics, Iamblichos, Plato, and Aristotle. The term *charten agraphon* was employed by Aphrodiseas many centuries before Locke employed its Latin synonym *tabula rasa* (Georgas, 1995).

Among all the ancient Hellenic philosophers, Aristotle is acknowledged as the most accomplished in defining and systematically studying the phenomenon of psychology. However, this chapter deals with modern psychology in modern Greece. The establishment of modern psychology is ironically probably delayed because the philosophers at the University of Athens emphasized the importance of the Greek philosophers to psychology. While in the 1950s and the 1960s psychology separated from philosophy at many American and European universities, it took Greece until 1983 to establish divisions of psychology within departments of philosophy, education, and psychology. In 1987 the first autonomous Department of Psychology was created at the University of Crete. All major Greek universities (i.e., Athens, Thessaloniki, Ioannin, and Crete) now have a department of psychology. These departments run four-year graduate programs leading to a degree called *Ptychio* (Masters degree). In addition, programs leading to the Doctor of Philosophy are awarded at all of these universities.

Because psychology was late in becoming a discipline in itself, one should realize that the majority of Greek psychologists are trained abroad. The largest group has been trained in France, followed by a second group trained in the UK, followed by Germany, the USA, and Canada. One could say that in Greece, psychology is a kaleidoscopic assembly of different theoretical schools and practical applications. The majority of psychologists in Greece (around 800) are members of the Association of Greek Psychologists. Members have to have a degree in psychology at the masters level. A second association was established in 1991, the Hellenic Psychological Society, whose members are university faculty members and psychologists in research centers. The minimum criterion for membership is a Ph.D. in psychology.

A law which licenses psychologists to practice was passed in 1979, regulated by the Ministry of Health and Welfare. However, it only came into force, primarily because of the problems in delineating the specific types of "psychological work" of the three main fields: clinical psychology, educational psychology, and organizational psychology.

Psychologists in Greece work in a variety of settings. By far the largest number are clinical psychologists. The first mental health centers in Greece were established in the 1950s and subsequently the Institute for Child Health and several private mental health centers were also established. Most clinical psychologists are employed in mental health centers. Only few of them combine a full-time position in the mental health or hospital system with a private practice (Georgas, 1995).

2.29.3.6 Italy

Most of the following information is based upon an article by Avallone (1993). In order to understand psychology in Italy one needs some historical background. As in other countries, one might say that experimental psychology started in the second half of the nineteenth century. The first theoretical paper *La psicologia come scienza positiva* by Roberto Ardigò was published in 1870. The first Italian psychological journal appeared in 1905, *Rivista Italiana di Psicologia*, and in 1912 *Psiche-Rivista di studi psicologici*. In 1906, the Fifth International Congress of Psychology took place in Rome and the first three academic chairs were created in Rome, Naples, and Torino. Psychology was introduced in schools and institutions. Mental tests were translated and developed, and in 1910 the Italian Psychological Society was founded. During the first world war in 1915 psychological tests were used to select army personnel, but then the development seemed to stop. The strong influence of the philosophical tradition, but even more due to the influence of the neoidealism (=fascism) and the second world war, negatively influenced the development of science in general and psychology in particular. There also existed an almost traditional dichotomy between pure basic research and applied research resulting in a professional practice without a methodology or theory. It was not until 1971 that one could study psychology in Italy resulting in a graduate degree in psychology. Even in the 1990s the majority of professors in psychology have their primary background in philosophy or medicine. As of 1971 there was a four-year program in psychology, divided into experimental, educational and applied psychology. After the need for a better curriculum became apparent, the four-year program was increased to a five-year program in 1985. At the end of a two-year *propadeuse*, the student studies for another three years in one of the following areas: (i) general and experimental psychology (about 8% of the students); (ii) developmental and educational psychology (15%); (iii) clinical and community psychology (62%); and (iv) work and organizational psychology (15%). Like in other European countries, a stereotypical interest in clinical psychology is seen (Carli, 1987), showing that being a psychotherapist is the ultimate goal of many psychology students.

From 1985 to 1996, the number of universities offering a psychology program increased (Torino, Trieste, Padova, Bologna, Cagliari, Rome, Palermo). In 1996, 11 universities offered a psychology program. Apart from the regular curriculum, Italian universities offer *Corsi di Perfezionamento* allowing students to specialize even further during at least one year. The *Scuolo di Specializzazione* offers a limited number of students to specialize during three or four years in, for example, clinical psychology. The *Dottorato di Ricerca* prepares the student for a research career. Apart from these university programs which are available for a limited number of students, many private programs are available in order to become a psychotherapist in almost any thinkable form of therapy.

In 1989 the State intervened by law, regulating the psychological profession; only psychologists with an academic degree were allowed to be registered in the official register.

Psychotherapists are only registered after an additional four years of university or university equivalent (State recognized) training. Because of this, the new generation of psychologists in Italy can claim a solid base in science for their applied activities.

The major applied area is clinical psychology with many psychologists entering private practice after the State required four-year training. However, many clinical psychologists work for the State, province, and local health units in many health-related structures (being called mental hygiene centers for psychiatric assistance, because Italy had banned all psychiatric hospitals as a result of the antipsychiatry movement).

In Italy, the *Societá Italiana di Psicologia* (SIP) approved its deontological code on September 24, 1981.

2.29.3.7 Portugal

If one looks at the development of psychology in Portugal one should look at the time before and after the democratic revolution in April 1974.

Before the revolution, the State-run universities did not acknowledge psychology as a subject in its own right, it was only a subsidiary course in philosophy. However, several organizations, headed by the Catholic church, created a five-year degree course in psychology in the *Instituto Superior de Psicologia Aplicada* (Higher Institute of Applied Psychology, ISPA), which had evolved from the "Pedagogical Higher Institute" which was founded in 1962. Public universities did not start a psychology program until 1977. Consequently, the majority of certified psychologists claiming a degree in psychology between 1969 and 1982 received their training at the ISPA. These psychologists are assembled in the official but small *Sociedade Portuguesa de Psicólogos* (Portuguese Psychological Society, SPP).

Following the revolution, the proposal to create a psychology course at the public universities was made. In 1977 the psychology course was offered within the framework of the Faculties of the Humanities. A little later the course was offered by the newly created Faculties of Psychology and Educational Sciences (FOCE). In the meantime, psychology degrees were still awarded at the ISPA, which by now was detached from the Catholic founding organizations. At the same time a new *Sindicato Nacional dos Psicólogos* (National Union of Psychologists, SNP) was founded in order to assemble all practitioners of psychology together; those with a psychology degree from ISPA, those with a philosophy degree from State universities, or those with a psychology degree from public universities after 1982.

Rivalry between psychologists from public universities and psychologists from the ISPA resulted in a law recognizing the equality of the ISPA degree with the public university degree. In the context of this competition, the *Associaçâo Portuguesa de licenciados em psicologia* (Association of Psychology Graduates from Public Universities) was established in 1982. The *Associaçâo Portuguesa de Psicólogos* (Portuguese Psychological Society, APP) was also founded.

Once the relationships among psychologists started to improve, members of the Association of Psychology Graduates from Public Universities changed their association into *Associaçâo de Psicologia Portuguesa* (Association of Portuguese Psychologists, APPORT). More recently the Portuguese Society for Clinical Psychology was founded. In 1997 work is in progress to establish the *Ordem dos Psicólogos* (Association of Professional Psychologists). In order to create a single representative body, four of the Portuguese psychological organizations joined forces, thus establishing the "National Board of Psychologists." The purpose of this Board is to draw up the statutes of the "Association of Professional Psychologists."

From the above one can see that the situation is quite complex in Portugal. Because of this it is almost impossible to produce realistic figures and data. There is a rumor that Portugal has about 4000 psychologists, but an estimate of 2500 seems more realistic. In 1996 there were about 3000 undergraduates in psychology. After a five-year program about 600 get their degree every year.

Most psychologists are employed in the educational sector and within organizations in the private sector. The situation with regard to clinical activities is unclear.

The title of "psychologist" is semiprotected. In order to be employed as a psychologist, one has to have an official document called the *carteire profissional* (professional certificate) issued by the Ministry of Work. However, illegal practice does not entail any legal consequences. Hopefully the establishment of the Association of Professional Psychologists will improve this situation (Pereira, 1995).

Four universities offer a psychology program: Lisboa, Porto, Coimbra, and Ispa. The program takes five years and there is a fixed number of entrants.

2.29.3.8 Spain

The current trend in psychology is intervention oriented. This intervention is, due to the specific developments in science in Spain, very technically oriented. In order to understand this development one has to focus upon the scientific dimensions of fundamental psychology in Spain. The emergence of scientific technology became the social justification for psychology as a profession. Standard studies about the history of psychology in Spain usually start with Sénèque, followed by the Renaissance, and ends by analyzing the last 100 years. If we concentrate on the period in which the current discipline of psychology is constructed, we can distinguish two periods.

The first period started at the beginning of the twentieth century until the Civil War (1936–1939). The second period started in the late 1940s to early 1950s, and ended with the Franco regime in the second half of the 1970s. During this period Spain was isolated from the scientific world. The transition to democracy coincided with the start of independent psychology departments. In Spain there exists a rich tradition studying psychological phenomena from a philosophical, medical, historical, and even a literary background. This rich tradition has prevented the modern development of psychology for many years.

As a major event the Spanish psychologists mention the XIe International Psychology Conference planned to take place from September 6 to September 12, 1936 in Madrid. Cajal was president at that time. However, due to the Civil War, the conference was canceled and took place in 1938 in Paris.

The creation of the Spanish Psychological Society started in 1950 and the bylaws were published in 1952. In the following years within the Official College of doctors and licences in philosophy a section of professional psychologists started. In the meantime other psychological associations were created. All these different societies and associations formed the *Colegio Oficial de Psicólogos* (COP) in 1979.

It took until May 1979 that by a Décret Royal psychology became an independent discipline within the university system. Psychology is taught in at least 20 universities and institutions. Within 10 years the number of registered students in psychology increased from about 1000 in 1977 to over 5000 in 1988. The number of doctorates increased from 13 in 1977 to 139 in 1987.

In 1980 the university education in psychology, resulting in a licence, was recognized by law (BOE, April 14, 1980). Each university faculty confers the degree of *Licenciatura en Psicologia* and the COP legally confers the protected title of *Psicologia*. There is still an enormous interest in psychology with more than 39 000 students in 1996 compared to initially 100 students. Currently, there are more than 35 000 psychologists in Spain. The same is true for the Spanish Psychological Societies. The COP and the *Colegi de Cataluña* had about 4500 members in 1981 and now have more than 25 000 members. Spain has probably the highest percentage of psychologists per capita (about 575 psychologists per 1 000 000 inhabitants) in the world.

Because psychology is a young discipline the average age of the Spanish psychologist is quite young. About 30% are below the age of 30, while only 15.4% are older than 40 years. Psychology attracts more women than men (63% women). Of the women the majority prefer to work as school-psychologists or pedagogues (41%), and in traffic and safety psychology 84% of psychologists are female. Clinical psychology is preferred by 37% of the students. Rehabilitation psychology attracts about 18%, while organizational psychology, social psychology, and forensic psychology each attract only less than 10%.

The percentage of unemployment among psychologists is not too bad; only 10.5% vs. 17.3% in the active population and 10.5% vs. 13.6% of the academic population. But this situation will change soon. Among the younger generation of psychologists (younger than 25 years of age), the unemployment rate is high (37.5%). Psychologists have to focus upon new applied areas. There is still an overemphasis in educational psychology, pedagogics, and clinical psychology. This might be the reason why 53.7% of the clinical psychologists work in private practice. More attention should be paid to organizational psychology, social services, justice, and traffic psychology, while there is hardly any interest for environmental, sports, forensic, or military psychology. It is only these new areas that still offer job opportunities.

The first step towards a deontology for Spanish psychologists was set during the first National Psychology Congress in Madrid in 1984, were Alfredo Fierro presented a paper called *Deontological Code* (first draft). Many discussions followed and in 1987 a taskforce of 100 experts got together in Madrid, resulting in a proposal that after elaboration by Alejandro Avila (president) was presented to the Government Board of the *Colegio Oficial de Psicólogos*. The board ratified this proposal.

2.29.3.9 Switzerland

The following observations are based upon a periodically conducted investigation into the employment possibilities for Swiss recent graduates by a working group for academic career counseling (Diem, 1995).

The 1988 sample had a reply rate of 60% and among the 4856 responding graduates, 200 of them were psychologists. Although the unemployment rate for psychologists one year after they graduated is only 5.5% for Swiss standards it is almost twice as high as the average unemployment rate of 3%. Especially when there is an economic recession, like in 1985, the unemployment rate among psychologists was as high as 12%. The major employers for psychologists are universities (20%), social services (42.3%), health services (14.1%), private services like banks and insurance companies (7.9%) and schools, as teachers (7.3%). For 35% of the jobs recently occupied by psychologists, no academic degree was required. Also psychologists are more frequently employed on a part-time basis which is related to the high percentage (68%) of women in psychology (in all other academics an average of 31%). Overall, academic women engage in part-time work (up to 40%), while the figure for men reaches 21%. The higher contingent of women can also explain the lower average income of psychologists. A study by the *Arbeitsgemeinschaft für Akademische Berufsberatung* reveals that women earn about 20% less than men in all employment areas.

The Nationalfond study *La réussite professionnelle des économistes, juristes, médecins et psychologues* (Berberat, Goldschmid, Neirynck-Carton-de-Wiart, Nughes, & Ricci, 1990) gives us some information about the labor market for psychologists. The subject sample comprises 332 psychologists (179 women) who completed their studies at a western Swiss university between 1949 and 1989. It regards exclusively members of the Federation of Swiss Psychologists (*Föderation Schweizer Psychologinnen und Psychologen*, FSP). Almost all of them were employed. Twelve percent worked at Universities or Research Institutions, 30% in education psychology or social services, 21% in private practice, 13% in hospitals and clinics, and 14% in the schools. As one can see these figures differ slightly from the general situation in Switzerland mentioned earlier.

2.29.3.9.1 Clinical psychology in Switzerland

Compared to other countries in Europe, a relatively small percentage (13–14%) of the psychologists are working within the health services. This might be due to the fact that in Switzerland the foundation of clinical psychology was laid by medical doctors. Initially psychologists were only allowed to work with aptitude tests. In the 1950s, psychologists were allowed to enter into psychiatric treatment, initially as diagnostic experts, but later on they increasingly applied themselves to psychopathology (originally a medical discipline). More recently psychotherapy was added to their repertoire. Seen as a whole, the relationship between physicians and clinical psychologists is still largely a dependent one and clinical psychologists tend to represent a marginal group in psychiatric institutions.

In private practice the competition is unequal. Medical doctors' work is entirely compensated by health insurance companies, while psychologists' services are often only partially covered or not compensated at all.

In the research area the picture is totally different. They either work at universities, in research departments of psychiatric clinics, or in clinical research funded by industry. Psychologists' thorough training in methodology is highly respected. Another problem in Switzerland is that the title of "psychologist" is not protected by law.

2.29.4 CONCLUDING REMARKS

Looking over past developments in Europe with regard to psychology in general and clinical psychology in particular, we see some trends emerging. First of all we can see that all over Europe the professionalization of psychology is taking place. Most of the time the professionalization is triggered and catalyzed by clinical psychologists interacting with public health organizations. In order to guarantee a professional high standard of psychological expertise, official registers of psychologists are contrived. Although the need for registration is most strongly felt within the health care services in several countries, this format of registration is extended to all psychologists or for several specializations within psychology.

Another trend we see is that the registration, initially coordinated by national psychological societies, is increasingly done by the official governmental agencies mostly in coordination with the national psychological societies. In some countries the registration leads to protection of the title "psychologist," in other countries only some specialty areas within psychology are registered. Usually registration by law of the title "psychologist" is automatically related to quality control mechanisms.

With regard to education we see an increasing tendency all over Europe to shorten the study time (mostly six to seven-year programs revert to four to five-year programs). In countries where they maintain a longer curriculum, a numerus clausus or numerus fixus is instituted. The consequence of this shortening of the study time is that most studies are considered to be inadequate and/or insufficient. Because of that, additional training programs are developed and required in order to become a registered psychologist. In that case there is always a fixed total with regard to the number of potential candidates who are allowed into this additional postdoctoral training program. So far, a system of continuous education is not officially instituted in Europe.

The kind of work psychologists are doing is diversifying rapidly (e.g., traffic psychology in Spain), but still the majority of psychologists work in health-related areas. In many countries psychologists are still an extension of medical doctors but increasingly it is observable that psychology is recognized as a specialty by its own right, and that the psychologist is paid through the health system and health insurances directly (however, many times only after a referral by a medical doctor).

Next to the increase in the health-related area, we see an increase in private practice: sometimes a single-person practice but often a group practice sometimes even with other health-related professionals. This form of privatization is due to the fact that government institutes hire less people on a tenure basis. Often the official governmental institutions prefer to subcontract special orders/requests to a private organization.

The third area of expansion is in research. The healthcare world, but also (pharmaceutical) industries, are becoming aware of the excellent research training many psychologists in many countries get. This is also one of the few areas where within healthcare there is no competition between medical doctors and psychologists. Psychologists are by virtue of training far better researchers.

I should also say something about the change within clinical psychology itself. It used to be a soft discipline with all "funny" kinds of psychotherapy, and it was hard to prove that they did any good to the clients/patients. But due to financial cut-backs in the more hardcore areas of experimental and research psychology, many experimental, cognitive, psychophysiological, personality, and neuropsychologists showed a clinical inclination/interest which had a strong modifying effect.

All of a sudden assessment became more important, diagnosis was allowed and even mandatory later on, treatment effects were evaluated, theoretical backgrounds were studied, rehabilitation programs and treatment programs were based upon scientific theories from neuroscience, cognitive psychology, or personality psychology.

Although psychology grew in the bosom of philosophy and moved from there into social and educational sciences, by now clinical psychology is becoming a β-science with a very close relationship towards neurosciences.

The above mentioned developments are strongly supported and often initiated by the European Federation of Professional Psychologists Associations (EFPPA). In 1993 Member Associations of the EFPPA were: from Austria the *Berufsverband Österreichischer Psychologen*, from Belgium the *Belgische Federatie van Psychologen—Fédération Belge de Psychologues*, from Denmark the *Dansk Psykologforening*, from Estonia the Union of Estonian Psychologists, from Finland the *Suomen Psykologiitto ry*, from France the *Association Nationale des Organisations de Psychologues*, from Germany the *Berufsverband Deutscher Psychologen*, from Greece the Association of Greek Psychologists, from Hungary the *Magyar Pszichológiai Társaság*, from Iceland the Association of Icelandic Psychology, from Ireland the Psychological Society of Ireland, from Italy the Italian Network of Professional Psychologists' Associations, from Liechtenstein the *Berufsverein der Psychologen Liechtensteins*, from Luxemburg the *Association des Psychologues diplomés*, from Malta the Malta Union of Professional Psychologists, from the Netherlands the *Nederlands Instituut van Psychologen*, from Norway the *Norsk Psykologforening*, from Poland the *Polskie Towarzystwo Psychologiczne*, from Portugal the *Sindicato Nacional dos Psicologos*, from Slovenia the *Drustvo Psihologov Slivenije*, from Spain the *Colegio Oficial de Psicológos*, from Sweden the *Sveriges Psykologförbund*, from Switzerland the *Föderation der Schweizer Psychologen*, from Turkey the Turkish Psychologists Association, from the UK the British Psychological Society, and the Affiliate Member, the Israel Psychological Association.

ACKNOWLEDGMENTS

I would like to thank the quoted authors for their indirect contribution. I hope that, due to limited space, I did not do injustice to the refered articles. Any misquotation is my own responsibility.

2.30.6 THE FUTURE 362

2.30.1 INTRODUCTION

Clearly, there is probably more than one way to develop and maintain a practice during these troubled times in the healthcare arena; what follow are ideas, attitudes, and systems that have worked for one group practice in Ohio. The goal of this chapter is to expose the reader to the enormous potential available to a psychologist along with the techniques for the maintenance and survival of an independent practice in the 1990s. To do that, a historical view or developmental perspective, coupled with a biographical sketch, is taken. The evolution of the practice of psychology may be gleaned elsewhere in these volumes, for example, the evolution from freedom of choice legislation to ERISA to the chapter on managed care, but in this chapter, the reader will discover the need to continually "stroke"—never just to "tread water." The concept of the need for a strong working philosophy along with different processes and "products" will be discussed to illuminate the types of projects and attitudes that have been the driving force for this practice.

2.30.2 CONSIDERATIONS IN ESTABLISHING A PRACTICE

When I initially opened the doors of the practice, a number of considerations, attitudes, and preconceptions drove my decisions.

2.30.2.1 Location(s)

I wanted to be within 30 minutes of population groups to make the office(s) easily accessible.

2.30.2.2 Comprehensive Service Base

I wanted to be a full service health psychology practice provider, enabling the referral source to recognize a mental/behavioral health need, having to only think of one provider. To that end, I knew that I needed male and female staff, child and adult therapists, and assessors and therapists with interest/expertise around varying presenting problems.

2.30.2.3 Comfort and Attractiveness for Me and for the Public

After working at a county hospital with a view of an air shaft from a hospital-green cinder block 12 ft × 12 ft room, I knew that I wanted my "suite of offices" to be pleasant for the staff and clients. My expectation was that the staff and I would be spending a lot of time there and it needed to be comfortable. In addition, I wanted the office to be no more than 10 minutes from home. This allowed me to never miss a dinner with my family and never miss participating in any school or extracurricular function of my children. In addition, I found the unattractiveness of the hospital insulting to the clients.

2.30.2.4 Hours of Service

In the current day and age of two working and volunteering parents, I also believed that it was important to have evening and weekend hours to be able to accommodate clients' work schedules (as long as it was not abusive to the therapist).

2.30.2.5 Overhead Surveillance

I have found that most people do not follow their overheads or pay attention to their costs. I wanted to be able to serve people in their locations with attractive offices at convenient hours, but I also wanted to keep a close eye on costs. These are not necessarily contradictory. Systems (to be described below) were put in place from the start to allow that to happen. Multiple locations do not mean duplication of support staff or equipment.

2.30.2.6 Responsiveness to Caller

Whether the caller was a referral source or a client, I wanted the clinical staff to return calls within three hours. To that extent, everybody was required to carry pagers. When cellular phones became available, the traveling and busiest therapists all were provided with them. Each therapist remained responsible (on call) for their own caseload. For the first 15 years of the practice, I took all after-hours calls not associated with a specific staff person. At this point, the calls are handled by the Director of Clinical Practice. Responsiveness also relates to commitment to the practice, and, therefore, I am not an advocate of part-time employees who work elsewhere. (I have an appreciation of part-time employees who parent the remainder of their time. Barring clinical crises, we attempt to respect their childcare commitments.) Those who work elsewhere invariably will be torn between loyalties if a choice needs to be made. If you have a clinician who works part-time for you and is a school psychologist during the day, the client or referral source may need to speak with this clinician who is not readily available. The practice of psychology, for better or worse, functions on a more immediate, need now basis. In addition, if working part-time elsewhere, issues of multiple malpractice exposure and coverage are a concern.

2.30.2.7 Income Consideration

It should be clear to anyone that when you are earning an income based on a fee-for-service time frame, you are limited in your total gross income by the time you spend. If the overhead is fixed and the office is available, your income can increase if you have somebody else working the space for you. In a solo situation, your income would be vulnerable when you are on vacation or out marketing. If others are providing service and income is being generated, you are still free to go about your life, knowing that money is still being generated. (More will be spent on this later as we discuss contracts for outside service as a method to pay overhead.)

2.30.2.8 Values and Ethics

Do not compromise your values or your ethics for anything or anyone. Do not contract with providers or referral companies (i.e., employee assistance programs (EAPs) or managed care companies) who ask you to do things that you believe are questionable. One managed care company wanted us to submit signed HCFA 1500s to them with no other information other than the subscriber's name filled out. Do not give in to clients who attempt to manipulate you or "the system." I had an adult client's insurance salesman father inform me that his son's benefit plan was bad and that I needed to bill a second session per week instead of just the one he was seen—"who would ever know"—to allow for higher reimbursement and less out of pocket expense.

2.30.3 COMPONENTS OF A PRACTICE

In an effort to orient you to the practice about which you will be reading, let me describe the nature and form of the practice as it currently exists. The author is the sole owner and shareholder of a professional corporation, incorporated under the laws of the State of Ohio in 1978. I was trained as both an experimental and clinical psychologist, and began my career in 1968 as a committed behavioral-oriented therapist (social learning theory *a la* Bandura; cognitive behaviorist *a la* Meichenbaum, Mahoney, etc.). The practice began and remained "health psychology"-oriented (having been trained by William House, Tom Hyde, and Barbara Melamed in the early 1970s). At present, the practice consists of the following divisions or departments.

2.30.3.1 Division of Clinical Practice

This is the division of the practice that delivers clinical services in our outpatient offices. The work performed in these offices may be funded by traditional general indemnity insurance, capitated arrangements that we have had and will continue to have, managed care contracts (either in the form of PPO or EPO as we have with one large Ohio insurer for its HMO product), assessment services to national or local EAPs, etc. This division accounts for 20% of the total fee income generated. At the outset of the practice this unit produced 75% of fee income the remainder being earned by the Division of Mental Retardation and Development Disabilities.

2.30.3.2 Division of Employee Assistance Programs

Marketed as a separate contributing component of the group is a state-wide EAP division that has a number of capitated contracts to provide broad brush EAP services to company employees and eligible family members. Currently, there are seven contracted companies, covering 12 000 lives. This division accounts for 20% of the total fee income generated.

2.30.3.3 Division of Legal Consultation

This division provides psychological consultation to legal referral sources, ranging from public agencies (i.e., workers' compensation, Attorney General's office, Common Pleas or domestic relations courts, Social Security Administration [as a group we do not conduct Bureau of Disability Determination evaluations nor any longer conduct Bureau of Vocational Rehabilitation evaluations], Department of Labor) to attorneys, specializing in various aspects of the law. This division of the practice provides service throughout the state of Ohio and accounts for 20% of the total fee income generated by the group.

2.30.3.4 Division of Mental Retardation and Developmental Disabilities

Believe it or not, this was the core of the practice when it began in 1978 with a grant from the Ohio Office of Developmental Disabilities. To this day, we provide extensive consultative and direct service to facilities—public (state and county agencies) and private not-for-profit agencies—throughout the northern Ohio region. At the time of writing, facilities for the mentally retarded and developmentally disabled are under contract to the practice. When an opportunity became available to provide OBRA-PASARR evaluations, we marketed our services throughout the counties of northern Ohio, and provided coverage to 24 of the counties for this specialized need. This division in the past accounted for 50% of the fee income of the practice, but due to federal and state funding cuts has been reduced drastically to approximately 25%.

2.30.3.5 Division of Long-term Care

Staff are placed in facilities that provide long-term care services to the elderly or disabled. This division of the practice provides service throughout the entire state of Ohio, and has also been made available as a "turnkey" operation to psychologists in other states. One particular group in Utah is up and running with eight contracts since first marketing three months prior to this writing. Our practice provides the direction, forms, manuals, contracts, marketing materials, and more to get the program going, and helps to maintain the momentum in the following months through direct consultation. Within Ohio as a function of Medicare cutbacks I have "sold off" 32 of my contracts and maintained only those eight in the greater Cleveland area to allow for greater profitability resulting from lower overhead to service. This division will vary in its contribution to the total gross fee income dependent upon reimbursement rates and the local fiscal intermediary rate of pay. (On January 1, 1997 the reimbursement rate for Medicare service billed from a Cleveland provider dropped 27%.)

2.30.3.6 Division of Practice Development

The author provides consultation to psychologists nationwide on all facets of practice development and management. Consultation ranges from issues of managed care contracting, capitation, staffing, sale of practice, and long-term care development. This contributes approximately 5% of the gross revenues for the practice.

I believe that it would be helpful to set the stage for the present form of the practice by observing it developmentally. To do this, the reader will be asked to participate in an autobiographical sketch of the practice and owner. Having spent five years as a psychologist on the faculty of Case Western University School of Medicine, Departments of Pediatrics and Psychiatry, I precipitously left in December 1978. At that time, I had a state-funded grant to provide behavioral consultation and treatment to public agencies and citizens with developmental disabilities. The state invited me to take this grant into independent practice and so the doors of the "group" practice opened in December 1978 with money to subsidize the overhead. We began with four clinical staff, one support staff, and 850 square feet of office space divided into two consultation rooms where outpatient psychotherapy was conducted and one waiting room/secretarial area combined, a co-existence that lasted for many years. We began by consulting to six public and private not-for-profit facilities for the mentally retarded and developmentally disabled citizens of northeastern Ohio.

As I write today, the practice has six locations, totaling 7000 square feet where outpatient psychotherapy is conducted (three offices for which I pay the rent, three of which are satellite offices using other's space and staff), and over four dozen contracted facilities where my staff practices psychology, located throughout the entire state of Ohio. The current payroll consists of 35 individuals, 85% of whom are full-time, all of whom are considered "employees" by the Internal Revenue Service (IRS) and hence paid by a W-2. During this period of almost 18 years, the practice has had two statewide capitated contracts (inpatient and outpatient benefits for chemical dependency/substance abuse and mental health) of two years duration, servicing 25 000 members of an HMO, and one regional (northeastern Ohio) capitated contract (outpatient benefit of mental health and chemical dependency/substance abuse only), servicing 45 000 members of an HMO and lasting four years. Currently, the only form of capitation is within one specialized division of the practice, the EAP Division.

2.30.4 GENERAL PHILOSOPHY

You must have a strong, workable general philosophy for making decisions. For the first five years that I was in practice, I maintained the belief that I was a psychologist running a small business. At about that point, I began to recognize and enjoy the reality that I was a businessman with a doctorate in psychology, running a complex business. Very early I recognized that I could not do this on my own. One characteristic of the entrepreneurial process is seeing and seizing opportunities. A general business philosophy needs to be developed that drives and directs the practice so that the psychologist can remain proactive. To be reactive and attempt to play catch-up will typically leave you behind. Much of what has happened to the typical psychology practices (typically solo in days gone by) had been telegraphed ahead of time. Unfortunately psychologists allowed disbelief and denial to blind us while outside forces took control of us, and again we need to react from a defensive posture.

The general philosophy of your business needs to consist of a proactive, organized, goal-oriented cognitive statement(s) that you create. The general philosophy takes thought and planning, and is a vitally important activity for which you must make time as you plan and grow. Within this philosophy is the basis for decisions that need to be made and why they are made, such as deciding on the demographics of the populations to be served. This can be based on the location in which you wish to work (i.e., neighborhood, office-sharing with potential referral source that will help determine your practice, i.e., pediatric practice, internal medical practice, pedi-gi practice, making certain that this arrangement does not violate any Federal laws about the arrangement). For a period of time, we had an Orthodox Jewish social worker in the practice who maintained hours on Sunday. His being with us and his available hours attracted members of the large Orthodox Jewish community in Cleveland. Another decision may be to rent in a nonbarrier free building, but the consequences of that decision should be fully weighed. In many urban and suburban areas, there is the choice of locating on a mass transit/public transportation line or not. All of our managed care credentialing forms inquire about accessibility to public transportation. We always respond in the positive, yet nobody asks what percentage of the client pool utilizes mass transit. We have noted that on average less than one client per month uses a bus. If the choice is to not be on this route, then you are saying something to your potential public and are probably eliminating a segment from your clientele which can be a good decision as long as it is a well thought-out decision.

Most psychologists that I have known over the years have pieced together full-time positions for themselves. Typically, many have had positions on hospital psychiatric services or in psychiatric hospitals. In both settings, the psychologist has more often than not been used as an assessor. One can choose how and where to piece together work. Frequently, daytime school psychologists maintain evening independent practices, each position complimenting the other and rounding out the type of work and the settings for these professionals. I have also known a number of hospital-based, university-affiliated, and government-employed psychologists who maintain part-time independent practices. You can decide on the hours you wish to work and the quantity you wish to work. All of these are directly related to your conscious decision about the work philosophy, the amount of money you wish to earn, and the lifestyle you desire. In some cases, this may be more externally determined than internally. With all of the overhead required by managed care companies (i.e., credentialing, case management, time on the phone, etc.), this part-time private practice venture on the part of psychologists may no longer be viable. When our group first opened in the late 1970s, it was not difficult to fill daytime hours. Now, with two working parents and with managed care companies looking for evening and weekend hours for their subscribers, prizing that as a parameter by which they will choose you as a therapist; as a profession, psychologists tend to be working more evenings and weekends than we might wish. In addition, many of these piece-together clinical positions have allowed for psychologists to maintain nonemployee status (outside subcontractor) with the owner of the practice from whom they office share or sublet space and receive referrals. Many managed care companies will not allow for that arrangement in that they require all providers to be contracted with them individually and, if a member of a group, to be carried on the group malpractice. Therefore, the flexibility of these part-time jobs is being threatened.

As managed care began to remove the freedom of choice of providers for subscribers, much of this decision-making, self-control, and philosophy-setting goals needed to be reassessed; not necessarily thrown out, but realistically reevaluated. As noted more thoroughly below, in the past practitioners could determine their market niche and appeal directly to that specific target niche. With managed care as the predominant referral source for most of the practices that I have surveyed, there is now a new target market to which to appeal, that is to say, the case managers and other controllers from the "dark side" who can now control your client flow.

2.30.5 STRUCTURE/ADVISORS/STAFFING

It is imperative that the structure and staff of a psychology practice change and mold to the ideas, projects, needs, and circumstances that you create, control, and do not control over time. Market pressures create factors that we do not control; they, too, will affect your staffing needs. I believe that there are a number of givens that are the necessary basis of a viable group practice: advisors/consultants, office manager, support staff, and clinical staff with consideration to level of degree, certification in specialty areas, sex, age, and so on. Each of these will be briefly discussed below.

2.30.5.1 Advisors/Consultants

I strongly believe that to succeed in business you must surround yourself with competent advisors and use them often. Issues of accounting and taxes, corporate structure, employment and labor law, leases (office space, equipment, and automobiles), contracting, Board of Psychology requests (and how to respond appropriately and legally), fiscal structure, and creation of a sensible ledger system (more will become clear as we go on) are the province of other professionals. We can only expect ourselves to know our field (not just "therapy," but the business of psychology) and to know when to use consultants. The Division of Practice Development allows me to interact with psychologists across the USA. It gives me insight into how sparingly our colleagues call on what is available to them—and financially feasible—in the form of business advisors. I frequently see how unaware psychologists are about how and why to use these consultants. The two most frequently needed consultants are accountants and attorneys. Both need to be willing to familiarize themselves with mental health issues, for example, State Board of Psychology (Social Work, etc.) Code of Ethics, regulations, and guidelines. My personal experience has demonstrated that a solo practice or small firm attorney or accountant is perfect for the majority of our needs. My observations have led me to the sound conclusion that we are not good clients for the large firms in that we do not generate enough fees, the rates we are charged are typically too high for our budgets, and we can get the equivalent, if not better, attention elsewhere.

2.30.5.1.1 Accountants

My experience has been that a mid-sized firm of accountants (the one I have used for my entire practice career consists of three partners and 10 additional staff), working closely with my Office Manager, have been able to create general ledger and detailed accounting information to allow me to evaluate the productivity and profit of each division of the practice and each element within. The general ledger that is done in-house functions in such a way as to interface with the information in form and substance that the accountant needs to produce quarterly statements, payroll tax documents, and other financial information that we might wish to utilize. After being in practice for 15 years and having done payroll in-house, I finally switched to a payroll company that prepares the checks and handles the compilation of taxes. With a state-wide business, we need to be paying city tax in multiple locations, and it soon became too complicated and costly to continue to do so in-house. Although it took some time and effort to coordinate and prepare for the transition, the use of an outside service has been cost effective for both my office manager, but more importantly, for my accountant. I believe the importance of that is self-evident.

The availability of cost ledgers, allowing you to evaluate the profitability of a segment of your practice, is a vitally important tool. This is true even if you have only one segment. As you diversify and expand into various market places, you will want to assess the wisdom of continuing in a specific arena and you will need important data to do so. Let me cite three examples: (i) "Yellow Pages" advertising may have gone the way of Edsels and long-term therapy (with all due respect to M. Seligman). With the advent of managed care, the concept of "freedom of choice" has almost disappeared from the subscribers' repertoire of behaviors. There are fewer subscribers allowed to open a phone book and choose a therapist in this day and age. In 1993, over six locations (five different counties, including two different phone companies), I spent \$27 000 in Yellow Page advertising. In 1994, on a rolling basis as the contract year ended, I reduced my cost to \$13 000 and the next year to \$7000. This decision has been driven by the data we collect in the office pertaining to profitability of the money spent in a Yellow Page advertisement. It became evident that we were not paneled providers for many of the potential clients who called from the Yellow Pages and to do so would have involved the creation of another full-time support staff position in addition to continuing advertising all the while managed care companies were dropping their reimbursement rates; talk about unpaid overhead. It was also evident that in some areas callers using the Yellow Pages had the highest no show rate. Also, we began to notice that those individuals who called were those without case managers to guide them, without insurance coverage, and unable to pay our fees. To that extent, it began to feel that the Yellow Pages were no longer a viable source of referrals. With a strong emphasis placed on tracking the intake system within the office (i.e., source of referral, source of payment, number of sessions, total revenue), we could more easily evaluate the profitability of a particular cost center.

Using the same approach, you can assess the profitability of, for example, an office location, contract, or staff person. If you review your goal statement and realize that you want to make a certain predetermined profit or spend only a certain predetermined percentage of income in a specific area, then evaluating the data of cost and income will allow you to make decisions objectively. But only by being true to your philosophy, by keeping an eye to those predetermined goals and percentages will you allow yourself the opportunity to profitably continue in practice. (ii) The second example where financial ledgers were of great value in decision making was in assessing the profitability of multiple locations. As population shifts occur, as employers close or as referral sources change, the initial reason for opening in a certain location may be changing or may have changed. Instead of simply paying rent on an ongoing basis, you will want a system to evaluate the wisdom of staying in a location. One reason for maintaining a location in the absence of "specific site" profitability is to allow you to continue to serve a referral source that refers to your practice in all locations, even if one is not utilized as much. If you recall the general overriding philosophy of making it easy on your referral source, you may serve yourself better by remaining open in a location and not forcing the referral source to differentiate where to use you and where to use another practice. It remains a simple referral process if the referrer can think "psychologist" and think only of you. (iii) The third example is contract profitability. The practice has contracted with a large, for-profit nursing home chain. Of the 16 of their homes that we service two examples of profitability issues need pointing out: (a) one location is a facility smaller in size than our criteria calls for, and (b) three of the facilities are being served by a "less profitable provider" (by virtue of license, we collect less at these sites, but due to geography, we are forced to utilize this person). Both situations are counterbalanced by the desire to service their entire company and, hence, some of the sites may be loss lead item. On balance, the entire nursing home chain is profitable. This can be assessed in your financial feedback established by the accountant and you.

One last thought on the valuable use of an accountant. Frequently throughout your development you will be approached by life/disability insurance salespersons. I submit that most Ph.D. level readers of this paragraph have little ability to evaluate and integrate into your investment strategies the type and amount of insurance needed. It is at this time that your consultant accountant can also be helpful.

2.30.5.1.2 Attorneys

Another consultant of great value is the attorney. My legal needs have varied over the year, but the basic function of an attorney for most practices would include reviewing leases (office space, equipment, cars [do not forget to have first passed the idea of leasing a car by your accountant to see if it is a viable method based on your financial situation, then go to the next and probably more expensive level of advisor], etc); creating employment contracts; contracts for facilities and companies that contract with the practice; discussion with accountant regarding issues of corporate structure, benefits, pension and profit sharing plans, life insurance; and so on. I have had two primary lawyers for the life of the practice. The lawyer I have used for 13 years has functioned as the consultant attorney to the state psychological association's Committee on Ethical Practice: Needless to say, he is well-versed in issues of mental health practice law and, specifically, psychology. I have worked closely with the attorney to minimize the size and language in a legal document to cover all the issues he believes are necessary to protect my best interests and yet to not frighten the other party away. I have found that most psychologists find legal documents daunting and would rather avoid any affiliation rather then feel trapped by a document they feel they do not understand and, hence, avoid.

At one point in my career, 15 years ago, the State Board of Psychology requested a site visit to investigate our compliance with supervision guidelines. My attorney suggested that I request all questions in writing ahead of time and his presence at the site visit. The Board never made that visit. The other attorney I use practices business and tax law in another state, but is well-versed in Federal guidelines and regulations, for example, tax, retirement, insurance. I have, over the years, used him, in conjunction with my accountant, to review life insurance documents prior to purchase. The issues of life and disability insurance being held in or out of a professional corporation has been dealt with by consultation between this attorney and the accountant.

Surprisingly, I have had little use of attorneys as collection agents (I have used three professional collection agencies over the life of the practice). The only two occasions during which I used attorneys for collections have been when I was owed money from companies with whom I had contracted and they terminated the relationship, owing me funds. I used an attorney in both situations and won court orders for payment (clearly written and enforceable contracts prior to the problem helped prevail in court).

2.30.5.1.3 Insurance agent

Although many of the readers will have found the APAIT malpractice to be sufficient, I never thought that it met all of my group's needs. For years, I have had a true group with multiple locations and levels of professional staff, and I have found that I needed a local agent who could sell professional malpractice from a company that also would cover renters, fiduciary, personal property, and liability (nonprofessional) all in one policy. It made more sense to me to have one company cover everything so that in case of a claim, two or more companies did not simply point fingers and assert that it was the other's responsibility. Therefore, I have always had just one company write all of my insurance for the employees and office on one policy, and have a local agent (only two across a 19 year span) handle any of the details involved therein.

2.30.5.1.4 Support staff

It was once explained to me by a close friend that you cannot do multiple full-time functions such as being a clinician, administrator, or marketer, all within a 40–50 hour week. What has allowed me to find and initiate the projects within the practice has been an individual who has functioned as the "runner of the practice." The Office Manager implements and follows up on all aspects of the practice with both support staff and clinical staff reporting to her for all administrative issues. What has worked exceedingly well has been my "initiator spirit" and her "implementer behavior." The Office Manager has had a number of functions in the practice, all additive until they get delegated to a support staff member who reports directly to her. The Office Manager came from a background of public relations. In addition to the administrator function in overseeing the hiring of all support staff and purchasing all equipment and supplies for the practice, the Office Manager has been intimately involved in all financial aspects of the practice. She has overseen all payroll and payables function in consultation with the accountant. The creation of the general ledger and the type of computer-based accounting system was something that the two of them devised with the awareness of the type of information I believed that I needed to make decisions about the practice. The payroll function that has now been contracted out is still coordinated by the Office Manager who prepares all the data (gross wages) for the payroll company. The Office Manager works closely with the accountant to file all tax payments in a timely fashion.

Personnel issues are all handled through and by the Office Manager. Once clinical staff are hired, they deal directly with the Office Manager to request such things as vacation, sick leave, supplies, and continuing education seminars. These decisions are made and implemented either in consultation with the divisional director, myself, or by herself. In addition, the Office Manager fulfills a strong public relation function, handling all referrals and special needs from attorneys who refer to the practice. This has allowed for a personal relationship between the attorney's office and a single representative of the practice. As we developed a number of state-wide projects (managed care capitated project in 1984–86, our state-wide nursing home business currently ongoing, and our state-wide EAP), the Office Manager has functioned as the liaison with the outlying staff and the contract facilities. There is a Clinical Director for all projects who is always available to the clinical staff if that is the need, but short of that, most requests are for administrative and informational items. The Office Manager typically is not in the field and, hence, is available to those callers. There have been a number of practice consultations that I have been contracted to do that has included the Office Manager. We were hired by a local defense attorney to help in a malpractice suit against a psychologist and his Office Manager. Both of us advised the attorney after doing a site visit and interviewing the psychologist and his Office Manager. Through the Division of Practice Management, I have been to a number of states. Follow-up consultation is done by phone and frequently involves the clinician or staff consulting with the Office Manager around a variety of issues she knows more about than me, for example, computer programs, accounting functions, contract forms. To that end, her time is hired out by the contractor.

Obviously a critical support staff person is the receptionist/intake coordinator. This individual fulfills three major functions in the group. In addition to doing all phone intakes, she also schedules all appointments (save for depositions and court appearances that continue to go through the Office Manager) plus she checks on all incoming clients' benefit plans. Phone intakes in a group practice that bears an individual's name are very tricky. More often than not, the caller asks to speak to or schedule with the principal (typically, that is to whom the client is being referred). The receptionist/intake coordinator is aware of each clinician's area of specialty by training, area of interest, and so on, and so directs the caller to the appropriate clinician. These assignment duties are always done in conjunction with the Director of the clinical practice and never on her own. Scheduling for all clinicians and all locations is done in one master calendar book (not a computer) by the receptionist/intake coordinator. Although I resisted for years, my support staff convinced me that it would be better for the office if we were to check the insurance benefits prior to scheduling clients, informing them of what we were told by the insurance company. This focuses on deductibles and copays and, hence, what our financial expectation is from the client at the first and then each subsequent session. It also avoids the managed care client accessing the office, even having the first appointment, before it is apparent that the client had a particular panel to which they had to go, etc. The receptionist/intake coordinator gets all of the documentation completed for the first visit when it occurs at our main office; the clinicians are responsible for all intake documentation (e.g., Consent to Treat, Fee Agreement, Releases, etc.) when they are working in our satellite offices. The receptionist/intake coordinator is the first line in making available community resources to our EAP clients. She, along with the EAP manager, maintains an updated compilation of available community services, attorneys, financial support systems, and so on. In addition, the receptionist/intake coordinator doubles as the typist for all secretarial functions in the Division of Mental Retardation and Developmental Disabilities (producing hundreds of reports and behavioral programs per year).

We have over the years utilized an individual to function as a secretary/reception support and typist to the remainder of the practice. In addition, she has over the years shared phone duty with the receptionist/intake coordinator, preparing intakes and providing resource information to our EAP clients. She does not schedule new appointments, but does assist in such things as reschedules and cancellations.

Most critical perhaps is the billing department. Over the years, the billing function has evolved from one of the many tasks the Office Manager did to that of a single staff person's job. As the practice became more complicated and as we grew into doing a great deal of Medicare work, we developed the need for a billing department. This staff person needs exceptional computer skills and a curiosity to make a commercial program work maximally for the practice. This individual needs to understand the goals of the billing office to be more than just mailing statements (electronically or by post). The billing office is the arm of the group that has the data by which you, as the owner, will make decisions about future movement. The manner by which this information is maintained and massaged will make the decision-making function of the owner easier. Commercial billing packages can provide more information than simply meets the eye as long as the person working it is inquisitive and daring. In cooperation with the Office Manager, these two individuals can create data presentations that tell "all the news, nothing but the news" about the practice. As noted above, we have begun to spend 50% of our billing time dealing with the fiscal intermediary for Medicare in Ohio. The billing staff person must be capable of negotiating the darkest recesses of an insurance morass; and must be able to understand federal manuals plus carrier regulations, and have the personality to pursue unsatisfactory answers to attempt to guide the billing procedures of the practice.

As an adjunct to this division of the practice, the owner has established and incorporated a separate business that is a billing business for mental health professional practices. The knowledge, hard gained from working within the Medicare arena and over 20 years of insurance business, has presented an opportunity that has been seized and stroked. Remember—never tread water.

2.30.5.2 Clinical Staff

This is probably the most difficult realm to maintain, specifically with the type and style of personnel with whom you want to attract and work. If you believe that your practice has something special to offer employees (e.g., information about professional psychology, business information that you believe is proprietary, procedures and documentation that is special and yours, etc.), you will want to utilize a "covenant not to compete" in each employment contract. Most applicants for a position resist this concept and counter with the argument that they would never "steal" your referral sources, ideas, forms, or client list. The basis of an employment contract is to prohibit that from occurring. The employment status of clinical staff has always been a clear issue according to the IRS, yet seen as murky for convenience sake by our colleagues. Most "employees" (whether licensed or unlicensed) in psychology practices are by convenience treated as "outside subcontractors" ("independent contractors"), but by IRS definition they are indeed employees. This status demands that the employer take out and pay taxes on behalf of the staff. This is a practice that most psychologists have resisted. Malpractice considerations are also important at this point. You need to check with your carrier because frequently an independent contractor cannot be carried on a corporate or supervisor's malpractice. This begins to present complications for contracting and securing work for the group versus the tax and employment status of those performing and billing for the service. Medicare has made it abundantly clear that all providers who are employed by corporate structures for the purposes of contracting and billing and who are currently in the position of supervising another staff member must enjoy employee status.

2.30.5.3 Continued Reading

In addition to the professional journals that we must continue to read throughout our careers, those running "businesses" must be exposed to business publications. Some of these are specific to your locale and others are related generally to the business of running a practice. The former consists of publications such as *Crain's Cleveland Business Weekly* and *The Wall Street Journal*; the latter consists of publications such as *Psychotherapy Finances* and *Behavior Today*. Divisions within the American Psychological Association provide publications with practice information that is relevant to you both from a clinical but also business point of view. As you see new procedures developing, you are confronted by opportunities of new business niches. The information you can access in these publications exposes you to opportunities that you would probably otherwise not see. If your practice has an EAP component to it, you will read about businesses that are expanding or moving into your area. You can be aware of physician group and hospital mergers by reading these papers and see potential opportunities for your practice—all of which can be followed up on, but not all of which will come to fruition. Priortize and then watch your ledger sheets. Frequently, medical practices or hospital programs (e.g., pain and rehabilitation programs, mood disorder clinics, etc.) advertise or put out press releases in these papers, again providing you with an opportunity to expand your services. Many of these programs are in need of a psychology component for the appropriate accreditation. With the mergers and movement of for-profit hospital chains, managed care companies, and other entities entering your geographic region, there are opportunities for you to market your services, expand your scope of practice or simply meet new referral sources. These are opportunities you might not be aware of unless you are exposed to these types of publications. In some areas of the country downsizing or more euphamistically "right-sizing" has provided opportunities for psychologists to create new business ventures and seize the moment.

2.30.6 THE FUTURE

As you read this, there are changes and opportunities going on around you. For example, what began as an excellent and lucrative business venture into long-term care (i.e., nursing home work) has become a much less profitable and questionable venture for those with alternative opportunities. Watching your ledger and consulting with your accountant will tell you when to get out or at least allow you the choice to stick with the project and continue to evaluate the potential therein. The practice owner needs to be one step ahead of the next disaster to be prepared to maintain income flow and profitability. One stays aware of the field by reading and volunteering. Involvement with one's state, local, and national professional organizations is not only a responsibility that we all bear, but it is also an opportunity that is waiting to happen. While on committees or at meetings with other state or local agencies or bureaus, for example, one will see business ventures waiting to happen. While legislative chair of the state association, I was involved and instrumental in having psychologists become providers for the industrial commission of the state. From that time forth, my group has done a great deal of work for that agency. One of my colleagues is positioned on the state association's state and federal agency committee. In that position, she has seen an opportunity with the forthcoming Medicaid HMO and positioned her practice to be a major player in that arena. One gets back multifold from giving if you simply see what is in front of you as opportunities for the growth and development of your practice. After consulting to a large state-wide homehealth agency about issues of managed care, we evolved into a joint venture contractual relationship having nothing to do with managed care. Opportunities abound. The exciting aspect of change and expansion is the opportunity to learn new skills, to meet new people, and create new business opportunities. There is no question that due to outside forces our profession is dynamic and our practices must be prepared to change. To stick with what we used to do because we thought it was a good idea and it was the "right thing" may not pay the mortgage. To be flexible and attempt to work with those empowered to control the marketplace to help them understand appropriate psychological services, ethical, behavioral, and sound clinical practice works to the betterment of the client, clinician, and profession. One can do that alone, in groups, and in organizational ways. You stand a better chance of effecting change if you work through and with your national, state, and local organizations; we are a large and getting to be a loud and effective national profession with which to reckon.

2.31.1 INTRODUCTION

The contemporary practice of psychology requires a prudent balance of traditional and emerging communication methods. Interpersonal interactions in the context of human relationship (e.g., speech, emotional expressions, and nonverbal gestures) have been a vital part of emotional healing throughout many centuries, and research findings in the 1990s underscore the importance of relational factors in effective psychological interventions (Whiston & Sexton, 1993). In addition to the time-honored interpersonal communication methods of professional psychology, rapid technological advances have propelled psychologists into another sphere of communication. Today's professional psychologist is increasingly expected to attain mastery in both of these communication methods—the very old and the very new.

It appears likely that technological changes will continue at a rapid or even an accelerating pace in the years ahead. This rapid rate of change suggests an ongoing need for psychologists to keep abreast of technological advances and the implications of these advances for professional practice. To this end, the American Psychological Association (APA) has published three editions of a software directory (Stoloff & Couch, 1992), the APA Practice Directorate has published *Organizing Your Practice Through Automation* (1996), national and international conferences have been established, and many journal articles and books on the topic have been published. Internet discussion groups regarding psychology and mental health practices abound, and the APA has charged the Media Psychology/New Technologies Committee of the Media Psychology Division to consider the implications of virtual reality, artificial intelligence, and other computer technologies. Psychologists are attempting to hold on to the value of established professional practices and communication methods while seeking the advantages available through technological advances.

Previous authors have distinguished between first- and second-wave innovations. First-wave technology allows for efficiency in maintaining records and office procedures but has little direct impact on clinical services. These technologies are now well-established and commonly used in the practice of psychology. They include office management computer software as well as facsimile, telephone answering, and voice mail services. Second-wave technologies have a greater direct impact on patient care and should be considered partially established in that many psychologists already use these technologies, though they will become increasingly prevalent in coming years. These include computerized assessment and interviewing tools, computerized therapeutic applications, telephone consultations, electronic mail, and clinical databases that directly impact patient care. Because of rapid technological changes, a third wave of technological advances must also be considered. This third-wave includes emerging innovations that have only started to affect the practice of psychology. Third-wave advances include teleconferencing, global networking environments (World Wide Web and Internet), virtual reality as a treatment tool, and innovative computer applications in training.

2.31.2 WELL-ESTABLISHED PRACTICE TECHNOLOGIES

A number of technological advances are now well-established as routine (first-wave) resources for professional psychologists. These include computerized office management systems, facsimile capabilities, and telephone answering and voice mail systems. The benefits and potential liabilities of each of these technologies are discussed below and summarized in Table 1.

2.31.2.1 Computerized Office Management

As early as 1987 a surprisingly high rate (90%) of psychologists surveyed in Canada were using computers for tasks indirectly related to clinical services including word processing, billing systems, and database management (Pollock & Maenpaa, 1990). It should be noted that the low response rate obtained in this survey research (23%) may have produced a spurious estimate of the number of psychologists using computers. Nonetheless, a decade has passed since the survey, and it is undoubtedly true that an increasing number of psychologists use computers in routine tasks associated with professional practice.

Word processing software allows a psychologist to reduce the time required for repetitive narrative. For example, a psychologist may use similar language in certain parts of clinical reports or treatment authorization requests. Rather than producing the narrative for each report, a template can be stored on computer disk and adapted for each individual report. Mailing merge options allow for personalized letters to be sent to various addresses for purposes of promotion or information. Also, word processing may improve the accuracy of written correspondence and reports. With tools such as spell checking, electronic thesaurus, and grammar checking, written documents can be scrutinized closely before leaving the psychologist's office. Word processing also allows for the evolving nature of forms and documents: For example, psychologists occasionally need to revise informed consent forms, release forms, or promotional statements. Word processing allows for such changes without requiring retyping.

Electronic billing software allows for the automation of the once tedious process of billing patients and health insurance carriers. Rather than typing or writing the patient's name, address, birthdate, and diagnosis on each bill, this identifying information can be stored electronically and automatically printed on a computer-generated billing form. Standard insurance forms are included in many software programs and printed onto plain paper with an inkjet or laser printer. In other cases the insurance forms are purchased separately and the printer is used to fill in the various fields in the standardized form. Most current billing programs and insurance companies also provide the option of electronic claims filing where the claim is filed via modem and no paper is transferred from the psychologist to the insurance company. Electronic billing promises to reduce much of the paper use traditionally associated with the billing process. Additional practice management software allows psychologists to keep electronic records of patient information, progress notes, financial records, accounts payable, payroll, and appointment scheduling (APA Practice Directorate, 1996).

Table 1 First-wave technologies: benefits and potential liabilities.

Technologies	*Benefits*	*Potential liabilities*
Computerized office management	Reduces time required for repetitive tasks Improves accuracy of written work Allows for evolving forms (e.g., informed consent) Billing efficiency, including reduced paper use Efficient management of patient records	Patient perceptions of increased bureaucracy Ease of duplication may compromise confidentiality and privacy rights In-session use of computers may inhibit patient–psychologist relationship
Facsimile	Immediate transfer of information (e.g., patient records)	Compromised patient confidentiality
Telephone answering and voice mail	Receive phone messages at any time without the expense of added secretarial support or answering services	Compromised patient privacy Technology failure may result in miscommunications

Although the use of first-wave computer software is commonplace in psychological practice, it remains important to consider the potentially negative effects of office computerization for patients. Because patients are generally less concerned about clerical efficiency than the nature of interpersonal interactions and quality of clinical services provided, some may experience highly visible computers as a bureaucratic hindrance or potential violation of privacy. Indeed, with the ease of duplicating electronic records there may be some legitimate basis for concern about violations of privacy and confidentiality. Also, some preliminary evidence from medical practice suggests that it may be important to avoid using computers for record keeping during the consultation itself. Physicians in the UK showed a diminished capacity to relate with patients when using a computer rather than pen and paper to issue prescriptions (Greatbatch, Heath, Campion, & Luff, 1995). Although this finding cannot be directly translated to psychological interventions, it is likely that using a laptop or notebook computer to take notes during a therapy session has an inhibiting effect on the human interactions that play an essential role in services provided by professional psychologists.

2.31.2.2 Facsimile

Facsimile (fax) machines are used to electronically transfer information to or from a remote site. The primary benefit of fax transmission is the immediacy with which information can be transfered. For example, a release form can be faxed to the office of another health care provider before holding a conversation about the patient, or patient records from a previous treatment can be instantly provided to the treating psychologist. Similarly, clinical reports can be faxed from a psychologist's office directly to the hospital floor or the referring professional's office. Contemporary computer software can make such transmissions paperless, with communications flowing from one computer to another.

The primary concern with fax transmission is the risk of compromising patient confidentiality. If a patient report is inadvertently sent to an incorrect fax station, for example, the psychologist has violated the patient's ethical and legal rights to confidentiality. This is especially likely with computer software that allows fax numbers to be stored in an electronic phonebook. Simply selecting the incorrect fax listing on the computer screen (with a single mouse click or keystroke) could result in sending a document to the wrong party and, therefore, in a violation of patient confidentiality. Even if the fax arrives at the correct office, the location and availability of the fax machine to office staff and others may compromise patient records. Because of these concerns, some jurisdictions have passed laws controlling fax transmissions of confidential materials. Thus, it is important for psychologists to know the legal guidelines of their regional or national jurisdictions. If faxing is legally permitted, it is incumbent on the psychologist to double-check the telefax number being used and to have a clear understanding of how the fax transmission will be handled on the receiving end.

2.31.2.3 Telephone Answering and Voice Mail Systems

Telephone answering systems allow callers to leave messages which can later be retrieved at the receiving end. The first generation telephone answering systems, usually depending on a cassette or microcassette recording of the incoming message, have become commonplace in many professional offices. This allows psychologists to receive incoming calls day or night without adding secretarial staff. In some cases psychologists use answering machines in lieu of an answering service. For emergency needs, an alternative phone number or electronic pager number can be left on the recorded greeting message.

The potential liabilities of using an answering machine for incoming messages include problems with patient privacy and technological failure. The patient may leave a message for the psychologist assuming the psychologist is the only one listening, especially if the greeting message is recorded by the psychologist. If a staff member or another professional in the office then listens to the recorded message, the patient may have disclosed information that was not intended for others in the office. Also, because low-cost answering machines have a relatively high failure or error rate, a patient or consulting professional may leave a message which the psychologist never receives. This breakdown in communication, caused by an uninformed faith in technology, can compromise patient care or even result in negligence in urgent situations.

Computerized voice mail systems have helped with both of these potential liabilities. Most voice mail systems have individual voice mail "boxes" which can be selected by the calling party. In addition, these boxes are usually password protected. These innovations reduce the inadvertent violations of patient privacy that frequently occur with low-cost answering machines. Computerized voice mail systems also reduce the likelihood of technological error because they depend on highly dependable digital technology rather than the mechanical and analog technologies used in free-standing answering machines.

2.31.3 PARTIALLY ESTABLISHED PRACTICE TECHNOLOGIES

A second group of technological advances are already used by many psychologists but will become more prominent in professional psychology. These second-wave technologies have more direct impact on clinical services than first-wave technologies, and thus also hold greater benefits and potential liabilities. Second-wave technologies, summarized in Table 2, include computerized assessment tools, computerized interviewing and diagnosis, computerized therapy tools, telephone consultations, electronic mail, and clinical databases.

2.31.3.1 Computerized Assessment Tools

In a survey of members of the Society for Personality Assessment and members of the Clinical Psychology Division of the APA, almost two-thirds of the respondents indicated that they use computers to assist with psychological testing (Ball, Archer, & Imhof, 1994). Over half used computers to help with test scoring and approximately one-third used computers to assist with test interpretation. Fewer than 10% used computers for test administration.

Many software programs are available for automated test scoring and interpretation. Among the most prominent test scoring and interpretation software is the Microtest Q system which generates reports for many tests, including the Minnesota Multiphasic Personality Inventories and the Millon Clinical Inventories. Two Rorschach software products are also widely used: the Rorschach Scoring Program (RSP) and the Rorschach Interpretative Assistance Program (RIAP).

One advantage of computerized test scoring for objective personality tests is improved accuracy. When Allard, Butler, Faust, and Shea (1995) had eight trained technicians and professionals hand score 43 protocols from the Personality Diagnostic Questionnaire-Revised (PDQ-R), they found 53% of the resulting profiles contained errors. Nineteen percent contained errors significant enough to affect clinical diagnosis—an alarming number of hand scoring errors. Hand scoring errors presumably affect other objective personality tests similarly, though it should be noted that the PDQ-R involves more complex hand scoring procedures than many other objective personality tests. In contrast to this high rate of human error, the error rate of computerized scoring is negligible (assuming correct data entry and software development).

Computers may also improve scoring accuracy of projective personality tests. Rorschach software such as the RSP and the RIAP provide algorithms to check for scoring inconsistencies. For example, a person may have coded both a whole blot response and a white space integra-

Table 2 Second-wave technologies: benefits and potential liabilities.

Technologies	*Benefits*	*Potential liabilities*
Computerized assessment tools	Greater accuracy in scoring	Unwarranted perception of interpretive accuracy
	Increases time efficiency	Use among unqualified users
	Access to interpretive expertise through expert system software	Changing professional identity
		Standardization assumptions may not hold with computer-administered tests
Computerized interviewing and diagnosis	More candid responses from patients	Greater difficulty in describing feelings and ideas
	Increases time efficiency	Possibility of excessive false positive diagnoses
	Increases screening of mental health needs in primary care	Must be quickly adapted to DSM changes
Computerized therapy tools	Used as an adjunctive tool for patient education, play therapy, cognitive rehabilitation, and behavior modification	Perceived as dehumanizing and reductive to those who view the human relationship as the essential ingredient of therapy
Telephone consultation	Immediate access to services	Lack of effectiveness data
	Decreases power differential between therapist and patient	Lack of nonverbal cues may inhibit emotional exploration or cause distractibility during session
	Gives privacy (or anonymity) to patient	May add to a sense of social alienation or dehumanization and thereby contribute to psychosocial problems
Electronic mail	As with telephone therapy	As with telephone therapy
		Unclear parameters for professional regulation
Clinical databases	Maintain personal outcome data to demonstrate effectiveness	Expense of equipment and on-line services
	Ready access to literature searches	Time required to input practice data

tion response but neglected to code the higher of the two z-scores. Rorschach software products detect scoring errors such as this and alert the psychologist or technician to the problem.

Computerization also reduces the time required for scoring psychological tests (Alexander & Davidoff, 1990). Whereas it might take 30–45 minutes to hand score a Millon Clinical Multiaxial Inventory, it can be computer scored in approximately five minutes. Similarly, the structural summary calculations for a Rorschach protocol may take almost an hour with a pocket calculator but only a few minutes with the appropriate software.

Test interpretation software provides psychologists with access to the interpretative expertise of test developers. Such software has been labeled "expert system" because it allows the computer to serve as an expert consultant to the psychologist. For example, Dr. John Exner has developed both the Comprehensive System for Rorschach scoring and the RIAP software that helps clinicians interpret Rorschach results. Similarly, Dr. Theodore Millon has been involved in the development of the various Millon tests (Millon Clinical Multiaxial Inventories, Millon Adolescent Clinical Inventory, and others) and in the development of the Microtest Q interpretive software. Automated interpretative systems such as these magnify the availability of experts for each test.

Despite these advantages of computerized test scoring and interpretation, legitimate concerns have been raised about these products and practices, especially regarding interpretative software. First, a computer printout may leave the psychologist with an unwarranted perception of accuracy. Although the scoring accuracy of well-reputed commercial products may generally be assumed, the interpretative accuracy may be suspect because the software developer has neither met the client being assessed nor had access to concurrent test results. Further, the interpretative narratives are often based on an expert clinician's personal experience with a test more than empirically validated results. Second, computerized test interpretation systems may unwittingly encourage the use of psychological tests among unqualified users. For example, a physician, marriage and family counselor, attorney, or social worker may attempt to bypass a psychologist's consulting services by gaining access to test interpretation software for the Minnesota Multiphasic Personality Inventory. To guard against misuse, test publishers closely monitor the qualifications of those who purchase test supplies and software. However, the publishers cannot monitor who actually uses the software once it is sold to the psychologist placing the order. Third, there is some risk that automated interpretative systems may move the identity of the professional psychologist toward that of a technician. At worst, a psychologist might administer tests, use computer-based interpretations, and write a report which includes much of the computer-generated narrative. This might involve little or no critical analysis and consideration of idiographic variables. The psychologist then would sign this report, thus taking legal and ethical responsibility for its contents, yet the computer-generated interpretative report on which the psychologist's report is based is not signed by a professional willing to share responsibility for the psychologist's conclusions and recommendations.

Lively interaction and debate will continue to play an important role in the development of professional standards for using technology in psychological assessment. Psychologists must collectively consider empirical evidence for computerized test interpretation and move forward with technological advances in a prudent manner.

Technological advances have shifted the debate from test interpretation software to automated administration of psychological tests. At the center of this debate is the question of test validity and standardization assumptions when administered by computer rather than pencil and paper.

It is unclear whether tests administered by computer produce comparable results to tests administered with pencil and paper. Sawyer, Sarris, and Baghurst (1991) reported only minor differences in Child Behavior Checklist scores when administered via computer, yet Davis and Cowles (1989) reported a greater tendency to "fake good" on a variety of personality tests administered by computer.

The burden to demonstrate that automated assessments do not significantly violate standardization assumptions rests on the profession of psychology and the individual test users. Under optimal circumstances each test would be restandardized and normative data collected for computer administration. A monumental task such as this would require many years and tremendous financial resources. But even this optimal solution may not completely address the problem because at least one study has found sizable differences among patients in the ways they respond to automated assessments (Spinhoven, Labbe, & Rombouts, 1993). Thus, renorming a test for computer administration may mask the significant individual differences in response styles. Spinhoven et al. (1993) recommend that a preassessment interview be used to determine if a patient is a good candidate for automated assessment.

The limited scope of this chapter does not permit a thorough analysis of other forms of computer-administered psychological testing. Promising areas of automated assessment include computer-assisted functional assessment (Smith, 1993), unobtrusive measurement (Meier & Wick, 1991), and behavioral assessment (Farrell, 1991).

2.31.3.2 Computerized Interviewing and Diagnosis

A variety of innovative diagnostic tools have been developed up to 1997. Some software is designed to be used as an adjunctive tool for diagnosis outside of the actual patient—psychologist interaction. Other software requires the computer to be used directly with the patient as a means for collecting information.

Software designed as an adjunctive tool for diagnosis is developed as an expert system in order to provide a structured algorithm for psychiatric diagnosis. First et al. (1993) report evidence of the effectiveness of the "DTREE: The *DSM* Expert," a computer-based expert system that guides clinicians through a series of decisions based on *Diagnostic and statistical manual of mental disorders* (*DSM*) criteria. Diagnoses obtained through a computerized system were compared with traditional diagnoses made during a case conference, resulting in a high rate of agreement, especially for patients with schizophrenia and major depression.

Software designed for direct patient use involves using the computer as interviewer in a screening interview. The self-administered Computerized Diagnostic Interview Schedule (C-DIS) is an adaptation of the original DIS, a standardized interview administered with pencil and paper. Preliminary research findings suggest that the computerized DIS produces data comparable to the original DIS (Bucholz et al., 1991; Erdman et al., 1992) and that adult

(Erdman et al.) and adolescent (Kight-Law, Mathisen, Calandra, Evans, & Salierno, 1989) patients respond favorably to computerized interviews. Additionally, there is evidence that patients disclose their concerns and symptoms more candidly in a computerized interview than in a traditional interview (Ferriter, 1993) and find a computerized interview less embarrassing (Erdman et al.).

Mini-SCID is a self-administered computerized adaptation of the Structured Clinical Interview for *DSM-III-R* (SCID) that can be used in screening for Axis I disorders. Unlike the C-DIS, Mini-SCID must be used in conjunction with the expert system DTREE (First, 1994).

A computerized version of the Diagnostic Interview for Children and Adolescents-Revised (DICA-R) has also been developed. Initial findings suggest that children find the computerized interview enjoyable and easy to use, and that reliability of results is respectable (Reich, Cottler, McCallum, Corwin, & VanEerdewegh, 1995). Comparability between the original and computerized versions of the DICA-R has not been reported up to 1997.

In addition to the obvious benefit of time efficiency and the benefit of increased patient candor discussed previously, a significant advantage of computer-based psychiatric diagnostic screening interviews is that they may ultimately help identify mental health needs earlier and more thoroughly. For example, if computerized psychiatric interviews were incorporated into primary medical care, it is likely that the mental health needs of patients would be more clearly and readily identified (Lewis, 1992).

One concern about computerized diagnostic interview tools is that patients report being better able to describe feelings and ideas to a human interviewer than to a computer (Erdman et al., 1992). In gaining efficiency with computerized interviews, there is some risk of losing the humanizing factors that have allowed professional psychology to prosper. A second concern is that the comparability of computerized interview data and human interview data has not been definitively established. Whereas two studies have shown comparability between the C-DIS and the DIS (Bucholz et al., 1991; Erdman et al.), a third study suggests that the C-DIS shows poor concurrence with the original (noncomputerized) SCID (Ross, Swinson, Larkin, & Doumani, 1994). Of particular concern is the high rate of false positive diagnoses made by the C-DIS. Finally, it should be noted that computerized interviews must be quickly adaptable to changes in *DSM* criteria. The computerized interviews described here were developed to fit *DSM-III-R* criteria, and will undoubtedly be adapted for *DSM-IV* criteria. Unfortunately, the process of changing the software could render obsolete much of the data supporting their usefulness.

2.31.3.3 Computerized Therapy Tools

Given the complexities of human interaction that are involved in effective psychotherapy, it is unimaginable to some psychologists that computers could ever be used effectively for psychotherapeutic interventions. Nonetheless, computer applications in psychotherapy have been steadily developing since the 1960s and are now used in some therapeutic contexts. The least controversial of these applications involves adjunctive educational programs to help prevent self-destructive behaviors and enhance desirable behaviors (Bloom, 1992). To illustrate, while waiting for an appointment with a psychologist a patient may find it helpful to participate in a educational computer simulation designed to enhance self-esteem, facilitate responsible sexual choices, or reduce alcohol consumption.

Others have found computers helpful to use adjunctively during the therapy session. For example, Kokish (1994) reports using a microcomputer as part of play therapy with children. Similarly, neuropsychologists and rehabilitation psychologists have found utility in using computer rehabilitation programs to restore executive functioning (Gianutsos, 1992; Giaquinto & Fiori, 1992).

Most controversial are the applications designed to replace or replicate part of the therapeutic intervention. Several programs have been designed to deliver behavioral and cognitive behavioral interventions (Bloom, 1992; Kenardy & Adams, 1993). These include the Dilemma Counseling System, designed to help patients choose between two unwanted alternatives, the Therapeutic Learning Program, used to reduce stressful interpersonal problems in the context of an educational group therapy setting, and a variety of specifically focused behavior modification programs used to treat depression, anxiety disorders, behavioral excesses, sexual dysfunction, and other problems. Some of these programs have been used in outcome studies that support their usefulness in providing therapeutic services.

Opinions about computer therapy tools will be partially determined by theoretical orientation. Those who see the human relationship as an essential part of the psychotherapeutic process are not likely to see great value in further developing therapeutic software. Moreover, they express concern that using computers as a substitute for human therapists is dehumanizing and harmful, robbing psychotherapy of the healing interpersonal process. Those who see the delivery of structured techniques as the active ingredient in psychotherapy are likely to be more encouraged by these recent software developments.

2.31.3.4 Telephone Consultation

Although telephones have been commonly available and an integral part of professional psychology for many years, interest in using telephones to deliver clinical services is a relatively recent phenomenon that is quickly gaining the attention of psychologists and professional organizations such as the APA. In a review of the literature, Haas, Benedict, and Kobos (1996) distinguish between telephone use as an adjunctive tool in therapy and telephone-only therapy. With regard to using the telephone as an adjunctive tool, telephones have been used for crisis intervention purposes, referral and screening purposes, and to provide services to established therapy clients when circumstances prevent face-to-face interactions. There is more controversy surrounding telephone-only therapy, which can involve either conventional therapeutic relationships conducted by telephone or pay-per-call services where the client is charged per minute of phone use.

One advantage is that telephone services can be obtained immediately. Rather than calling a psychologist's office to set an appointment several days or weeks in the future, a distressed patient can often make immediate contact with a psychologist offering phone services. Widespread availability of low cost cellular phone services further enhances the psychologist's availability to patients or potential patients. A second advantage is that the power differential between patient and therapist is reduced in a telephone exchange. No diplomas are visible, the patient has the power to hang up at any time, and the emotional intimacy is reduced by the absence of visual cues. Third, telephone therapy adds privacy (or anonymity, if desired) to the therapeutic encounter for those who might be concerned about being seen in the waiting room of a psychologist's office.

Each of these advantages has a corresponding disadvantage. Although there is little or no wait for telephone therapy, one might question the effectiveness of the treatment. Immediate ineffective treatment is no better than waiting for treatment. In the absence of compelling empirical effectiveness data, the question of whether or not telephone therapy works is largely determined by one's theoretical views of therapy. Second, though therapy may reduce the emotional intimacy and power differential of traditional therapy, it does so at the cost of eliminating virtually all nonverbal cues. Distractibility may be a greater problem without visual cues, and neither the therapist nor patient is able to experience the expressions or posture of the other. These factors may limit the emotional depth of exploration as well as understanding of transference and countertransference responses in the therapy process. Finally, although privacy and anonymity may be desirable to clients, one must contemplate the larger sociological dynamics that prompt this preference. Might the desire for anonymity (and the possibility that anonymous therapy can now be purchased) speak to a larger problem of social alienation and dehumanization that contributes to the same emotional problems that telephone psychologists purport to treat?

Several intriguing and promising applications for telephone therapy have been reported, including linking people with AIDS via conference calls (Rounds, Galinsky, & Stevens, 1991), providing support services for older adults (King, 1991), and even doing long-term intensive psychodynamic therapy by telephone (Spiro & Devenis, 1991). However, it is important that psychologists offering services by telephone observe all relevant ethical standards that pertain to providing psychological services. The long-term acceptability of telephone therapy will undoubtedly require persuasive empirical evidence of its efficacy.

2.31.3.5 Electronic Mail

The advent of electronic mail (e-mail), which consists of one person sending a message to another by way of a computer network, raises questions similar to those just discussed regarding telephone services. The Internet has made e-mail communication an easily accessible and global phenomenon. It is conceivable, for example, that a recognized expert in Rorschach interpretation could have a world wide consultation and supervision practice whereby psychologists from all over the world sent Rorschach protocols via e-mail and received interpretative assistance from the expert psychologist. Similarly, a psychologist might keep contact via e-mail with certain patients between therapy sessions, especially in rural settings where the traveling distances between patients and psychologists sometimes necessitate infrequent visits.

Most the advantages and disadvantages pertaining to telephone therapy also apply to e-mail services, except that even fewer cues can be retrieved from e-mail communications than from telephone (i.e., voice tone and inflection can be determined on the telephone). An additional problem, one that also applies to interstate or international telephone therapy, is the problem of professional regulation. When a psychologist in Switzerland offers supervision to a psychologist in the UK or direct services to a patient in the USA, in which country must the psychologist be licensed? To which national and state organizations is the psychologist accountable?

2.31.3.6 Clinical Databases

Although database computer software is commonly used by many psychologists to maintain patient and treatment information, additional clinical applications using database software are increasingly utilized in the practice of psychology. An excellent example is found among psychologists who maintain empirical outcome data for patients they treat (Clement, 1996). Although such databases do not lend themselves to controlled, double-blind outcome studies, they can be very useful in evaluating one's treatment efficacy with various disorders and types of clients. Moreover, as managed health care companies insist on assembling panels of competent therapists, the psychologist with positive outcome results will more likely be included on panels. Literature-based databases, such as PsychLit or various on-line services, are increasingly available for microcomputer use and can be very helpful in searching the literature for previous treatment approaches used for specific disorders. The variety and availability of other clinically relevant databases will expand exponentially as the Internet and World Wide Web grow in coming years. Potential concerns with clinical databases are limited to the expense of equipment plus on-line charges and the time required to input practice data.

2.31.4 EMERGING PRACTICE TECHNOLOGIES

In addition to the technologies discussed thus far, several other emerging technological advances may affect the practice of psychology in coming years. Third-wave technologies, summarized in Table 3, include teleconferencing, global networking environments (World Wide Web and Internet), virtual reality, and training innovations.

2.31.4.1 Teleconferencing

Teleconferencing, also known as videoconferencing, allows for visual and auditory communication through television monitors. Advances in electronics have made teleconferencing equipment increasingly affordable, resulting in experimental uses of teleconferencing among the health care professions. Whereas earlier prototypes required a satellite connection between television monitors, telecommunications can now be transmited much more economically through telephone lines.

Telecommunications are being used to offer medical care to some patients in rural areas of the USA. Technicians lead patients through diagnostic exercises while a physician observes and directs the examination from a remote location. Telemedicine saves travel time and money for many patients and makes medical care available to underserved areas. A similar concept has been developed at the University of Kansas (USA) to deliver neuropsychological services to rural areas. A master's level psychometrician leads a patient through diagnostic procedures while a neuropsychologist at the University observes and supervises the interaction. Patients have expressed satisfaction with the telecommunications services provided (Tröster, Paolo, Glatt, Hubble, & Koller, 1995). A similar strategy has also been used for remote cognitive testing of psychiatric patients in the UK (Ball, Scott, McLaren, & Watson, 1993). Teleconferencing also promises to provide an innovative means for continuing education for professional psychologists.

The primary benefit of telecommunication services is the availability of services and professional expertise to remote areas. Additionally, teleconferencing may enhance the availability of professional expertise around the world. For example, a patient in one part of the world may soon be able to consult with a leading expert in another part of the world about the symptoms he or she is experiencing. Similarly, psychologists throughout the world may participate in continuing education teleconferences with experts in various fields, thus raising the global level of professional expertise.

The main concern with teleconferencing relates to the setup costs. Although the telephone line costs of $10 to $35 per hour are not prohibitive, the site setup costs of $100 000 makes the widespread use of teleconferencing unlikely for most psychology practices, at least until the end of the twentieth century. Also, because most teleconferencing services are not yet covered by health insurance companies, there is little financial incentive for purchasing the necessary equipment.

2.31.4.2 Global Networking Environments

Computer networking allows one computer to communicate with another. The Internet is a

Table 3 Third-wave technologies: benefits and potential liabilities.

Technologies	*Benefits*	*Potential liabilities*
Teleconferencing	Can provide services to remote areas	Setup costs are high
	Will heighten the availability of professional expertise	Not yet covered by most health insurance companies
Global networking environments	May heighten awareness of mental health issues and resources May provide mechanism for supervision and consultation with other professionals	As with telephone therapy and e-mail (see Table 2)
Virtual reality	Provides the experience of *in vivo* exposure for phobias without having to leave the consulting office	Unknown generalizability of symptom relief
Training innovations	Promises to enhance learning and promote technological skills	Need to demonstrate didactic effectiveness

rapidly growing global network that allows communication among computers throughout the world. It is the electronic skeleton that allows for global e-mail communications and for the advent and growth of the World Wide Web. The World Wide Web is made possible by software innovations that allow information to be organized into "pages" which may contain text, graphics, video clips, sound, and connections with other web pages. Connections with other web pages, known as "links," usually appear as standard text printed in a distinct color. Thus, with a single mouse click the user can move from one web page to another. Because it is a global network, the user may (without knowing) be moving from a page in Australia to a page in Germany, then a page in the UK, then the USA and so on. This has led to the terms "web surfing" and "browsing." The software used to access the World Wide Web is called a web browser. Examples of web browsers include Netscape and Explorer.

With the growing use of the Internet and the user-friendly interface of the World Wide Web, many commercial services are now marketed on the Web, including psychological services. For example, Shrink-Link comprises a group of psychologists offering advice over the Internet for $20 per question.

In addition to direct services offered for profit, a number of no-cost resources are accessible through the Web. Newsgroups facilitate discussions among a variety of computers users throughout the world. Here one can find support groups for a variety of problems including depression, loneliness, addictions, and shyness. Professionals can subscribe to newsgroups or e-mail groups (called listserves) to discuss a variety of professional issues such as rural care, research funding, clinical training issues, and professional organizations. PsychNET, a service of the APA, provides free information on a variety of psychological disorders, lists and addresses of mental health organizations, and strategies for choosing a psychologist. Other organizations offer free self-help pages on a variety of topics. Some magazines and journals are available on the World Wide Web as well.

Because of the novelty and rapid growth of the World Wide Web, it is difficult to anticipate all the benefits and potential liabilities that will be forthcoming. What is clear is that the World Wide Web will continue to grow and will be a major technological influence on contemporary societies. Among the benefits for psychologists, it seems likely that the World Wide Web will make mental health information accessible to those who might not otherwise seek it. This heightened awareness of mental health needs may increase utilization of psychological services. Also, the Internet may become a mechanism for supervision and consultation among psychologists and other mental health professionals (Myrick & Sabella, 1995). The greatest liabilities of the Internet will probably be related to those who offer direct mental health services. All the concerns listed previously for telephone and e-mail consultations also apply for Internet consultations.

2.31.4.3 Virtual Reality

Virtual reality combines computer hardware and software to simulate real life experiences by presenting computer-generated graphics and sounds that are responsive to the movements and responses of the individual using the software. When using virtual reality, one wears a helmet that presents a visual field while simultaneously monitoring head movements. Moving one's head to the left, for example, would result in the visual field shifting accordingly. Many virtual reality systems also include gloves to monitor hand movements. In this way the user can pick up objects or move other objects aside while moving through the visual field.

Two reports of using virtual reality to treat acrophobia have recently been published (Rothbaum et al., 1995a, 1995b). By simulating graded exposure to heights, the researchers successfully provided many of the same benefits associated with *in vivo* graded exposure. Unlike *in vivo* interventions, virtual reality allows the treatment to occur in the office or laboratory while giving the psychologist greater control over the stimulus conditions. This appears to be a promising technology for psychology, with the only known liability being the uncertainty of generalizability to real life situations. Other applications of virtual reality in the practice of psychology are likely to be forthcoming.

2.31.5 TRAINING INNOVATIONS

Clinical training in psychology has already been influenced by the technological advances introduced by microcomputers, and it is inevitable that training advances will proliferate in the years ahead. Three types of training innovations are described here, though the list is not comprehensive.

First, one US university has developed a World Wide Web site for psychiatrists planning to take board certification examinations. The site provides sample questions and provides immediate notification of test results. A similar site for the Examination for Professional Practice in Psychology (EPPP) or other certification examinations would be helpful.

Second, a variety of simulations are available in which psychology students observe a situation on interactive videodisk and then are given options of how to best respond (see Engen, Finken, Luschei, & Kenney, 1994; Maple, 1994). Based on the option selected, they are then given more information and more choices. This type of learning environment is private enough to allow students to experiment with questionable options and observe the effects of their actions—something that would not be encouraged in real life practicum training. Many simulations are now available for training purposes, and many more are sure to come by the end of the 1990s. With the ease of newer object-oriented programming languages it is increasingly possible for psychology faculty to develop their own simulations without needing advanced programming expertise.

Third, expert system-based, computer-assisted training programs (ESCATs) utilize artificial intelligence technology to model the decision-making processes of experts in a particular subspecialty. Many aspects of professional training can be facilitated by ESCATs. For example, McMinn and Scanish (1996) developed The Rorschach Trainer, a feedback-rich tutorial program to help students master the scoring variables in Exner's Comprehensive System. There are varying levels of feedback that can be determined by the student or instructor. The Rorschach Trainer allows students to master much of the scoring system outside of the classroom, leaving more classroom time for teaching Rorschach interpretation. Todd (1996) describes the development and validation of an ESCAT to train clinicians to accurately diagnose eating disorders. As additional ESCATs are developed, specialized training may become much more interactive and practical than current lecture-oriented curriculum and continuing education programs. This could be especially important for psychologists practicing in remote areas where continuing education and in-person supervision are not readily obtained.

Appropriate and effective technological methods promise to enhance learning for students while simultaneously equipping them with technological skills to enter the changing mental health marketplace. With the rapid pace of technological advances, the biggest challenge for those developing training software will be to demonstrate the didactic effectiveness of the new training materials.

2.31.6 CONCLUSION

The tools of professional psychology are rapidly evolving in the midst of accelerating technological changes. Many new technologies can enhance the training and professional services offered by psychologists, especially for those who remain commited to the traditional tools, values, and standards of the profession.

2.32.1 INTRODUCTION

This chapter discusses the evolution of psychology as an organized profession in Canada, the development and financing of Canada's health-care system, the relationship of health-care policy to the practice of psychology and, in the final section, future directions, with primary care reform as an illustration of trends that will help shape the future of psychology as a major health-care profession in Canada. Professional psychology is presented in historical perspective in relation to Canada's health care system.

There has long been a dichotomy between Canadian psychology as a profession and as an academic/scientific discipline. A cohesive national strategy for the profession has been lacking, due in part to the structure of Canadian society, as well as the nature and functions of national and provincial/territorial psychology associations.

By way of framework, Canada's version of constitutional federalism, which makes this country one of the most decentralized federations in the world, is reviewed in order to show how Canada's health-care system evolved within it. The Canada Health Act of 1984, the legislative cornerstone of Canada's publicly funded national health care system (Medicare), is assessed in this context. Brief comparative reference is made to other modern health-care systems.

Health policy is discussed next in relation to psychology as a health-care profession. For funding purposes, psychology has been associated traditionally with mental health services. Fee-for-service psychological services in private offices have not been funded by Medicare, although psychologists most often are paid from public funds for services provided in public facilities (e.g., hospitals). In general, Canadian health-care policy has not addressed psychological services explicitly. This has limited the public access, especially to primary care services provided by psychologists. Alternative methods of payment for psychological services are under consideration.

The concluding section addresses the future. For all the health professions, primary care reform is already a major issue throughout Canada. A strong emphasis on primary care is of considerable interest to Canadian psychologists, most of whose clinical services fall within definitions of primary care. In addition, the reduction of domestic and international trade barriers will likely prompt greater mobility and lead to greater emphasis on empirically supported approaches and competency-based credentialing.

2.32.2 THE ORGANIZATION OF PROFESSIONAL PSYCHOLOGY IN CANADA

A global review of psychology in Canada was recently provided by Adair, Paivio, and Ritchie 1996). It notes that the development of Canadian psychology as a profession has been distinct from its evolution as a discipline. This dichotomy, which has existed since at least the 1940s, as well as the tensions and debates surrounding it, have been captured in the reports of major discipline reviews (Appleby & Rickwood, 1968; Berlyne, Black, Berry, & Douglas, 1971; Bernhardt, 1961; Ferguson, 1977; Macleod, 1955; Ritchie, Hogan, & Hogan, 1988a; Webster, 1967). It was only in 1994 that the convocation of a national conference devoted exclusively to Canadian professional psychology (Dobson & King, 1995) heralded a new era in its maturation.

Lacking a cohesive national strategy in its organizations and in the realm of public policy, professional psychology has developed piecemeal even though Canadian scholarly contributions to both foundational and applied psychology have been strong and cohesive. Adair et al. (1996) cited the structure of Canadian society as offering a partial explanation. Canada is the world's largest jurisdictionally defined land mass, with a small population base, two official languages, multiple cultures, and a decentralized political system in which the provinces are constitutionally responsible for health services. These features make any national undertaking difficult indeed.

As noted by Adair et al. (1996), events internal to the discipline also contributed to the history and status of Canadian professional psychology. The Canadian Psychological Association (CPA), unlike its counterpart in the United States, largely distanced itself from provincially-based efforts to establish psychology as a human services profession. Only in the 1970s did CPA initiate a slow and difficult shift toward greater involvement in professional issues. Since then, substantial achievements have taken place (Dobson & Dobson, 1993), although tensions between professionals and traditional scientists remain (Craig, 1993; Ritchie & Sabourin, 1992). A promising trend acknowledges the presence of multiple psychologies in Canada, stresses the links of applied psychology to university-based empirical traditions, and advocates for the strengthening of common ground between the practice and science of psychology (e.g., Dobson, 1995; Wand, 1993). This perspective is well anchored in the value that Canadian society attaches to pluralism.

Contemporary professional psychology organizations in Canada are described by Craig (1993). Wright (1971) captured their early history. They may be divided into two types: regulatory organizations with a statutory mandate of public protection, and voluntary societal organizations whose primary mission is to advance the profession. All regulatory bodies are established by and accountable to provincial/territorial legislatures, in keeping with the Canadian constitution. Some have dual regulatory and societal functions. Nationally, there are membership-based societal organizations and consortia or federations of provincial/territorial and national bodies.

2.32.2.1 Provincial/Territorial Organizations

Professional psychology organizations have been established in the 10 provinces and in one of the two territories. In two provinces (New Brunswick, Quebec) and in the Northwest Territories, regulatory and societal functions are combined in the same body. In eight provinces (Alberta, British Columbia, Manitoba, Newfoundland, Nova Scotia, Ontario, Prince Edward Island, Saskatchewan), there are distinct regulatory and societal bodies.

2.32.2.1.1 Regulatory bodies

Approximately 13 000 psychologists and psychological associates are regulated in Canada for the practice of psychology. Statutory professional regulation is decentralized by province/territory. By statute, the regulatory bodies typically exercise five major functions: determination of eligibility criteria for registration (e.g., degree, curriculum, supervised experience, examinations); registration of persons who meet the eligibility criteria; maintenance of a register of regulated psychologists and, where applicable, psychological associates; investigation of complaints against registrants; and discipline for incompetence or misconduct. In addition, they may develop and promulgate guidelines and standards of professional conduct, carry out fitness to practice investigations, monitor individual practices by means of mandatory or voluntary peer reviews, and offer or sponsor continuing education activities. The earliest regulatory board was The Ontario Board of Examiners in Psychology, established in 1960 and renamed The College of Psychologists of Ontario. The most recent regulatory board is Prince Edward Island's, established in 1990.

The most important requirements for initial registration of psychologists are an acceptable graduate university degree, supervised experience, and successful completion of written and oral examinations. A degree in psychology is normally required, although some jurisdictions may accept a degree from a program whose content is primarily psychological, even if the degree title does not include the word "Psychology." Four provinces (British Columbia, Manitoba, Ontario, Saskatchewan) require the doctorate; four (New Brunswick, Newfoundland, Nova Scotia, Prince Edward Island) specify the doctorate but allow registration on the basis of a Masters degree subject to prescribed conditions or for a limited period of time; two (Alberta, Quebec) and one territory (Northwest Territories) require a Masters degree. Specific curriculum requirements are variable.

Supervised experience requirements also vary across jurisdictions. Doctoral entry jurisdictions typically require one or two years of supervised experience, one predoctoral and/or one postdoctoral. Among the Masters entry jurisdictions, Alberta requires 900 hours of supervised postdegree experience; New Brunswick four years; Newfoundland two years postdegree until the year 2001, when the doctoral entry standard becomes effective; the Northwest Territories one year; Nova Scotia six years; and Prince Edward Island two years postdegree. In these jurisdictions, the supervised experience requirements for applicants with doctorates are generally similar to those of doctorate-only jurisdictions. Quebec, however, the province with the largest number of Masters psychologists in Canada, does not specify a supervised postdegree experience requirement. The Examination for the Professional Practice of Psychology is a requirement in all jurisdictions except the Northwest Territories, Prince Edward Island, and Quebec. Oral examinations are also used in all jurisdictions except Newfoundland, the Northwest Territories, and Quebec. In addition to registering psychologists, three provinces (Manitoba, Ontario, Saskatchewan) also register Masters level "Psychological Associates." In Ontario, the psychological associates are autonomous practitioners, except that they may not communicate a diagnosis unless this has been formally and individually delegated. In Manitoba and Saskatchewan, they practice under supervision.

The above picture shows considerable diversity across Canada. Indeed, nowhere is the historic absence of a cohesive national strategy for the development of professional psychology more evident than in the variable education and training entry levels for the practice of psychology across provinces and territories. Despite its repeatedly expressed intent to resolve this problem, organized psychology has been unable to do so. Greater uniformity in entry level criteria for psychologist registration may be achieved, however, due largely to the Agreement on Internal Trade (AIT) and its implications for the regulated professions including psychology. This wide-ranging trade accord was concluded in 1994 by the federal, provincial, and territorial governments. It proposes to eliminate barriers to the free mobility of regulated professionals within Canada, and it outlines processes both for the mutual recognition of professional qualifications and for the development of uniform entry level criteria across the country.

2.32.2.1.2 Societal bodies

The provincial/territorial societal bodies have been vital in promoting the development and advancement of professional psychology in Canada (Adair et al., 1996). The British Columbia Psychological Association was the first to be established, in 1938. World War II precluded further developments, until the Ontario Psychological Association (OPA) was founded almost 10 years later in 1948 (Wright, 1971). Thereafter, voluntary membership-based associations were created throughout Canada, before the advent of regulatory bodies. These associations were most influential in the drive to secure statutory recognition for psychology.

As societal bodies, the associations engage in advocacy and lobbying, provide direct benefits to their members, organize meetings, and offer or organize continuing education and other competence enhancing activities. By mandate, they protect the profession and help to secure its future. Their membership ranges from approximately 40 in the Prince Edward Island Psychological Association to more than 1200 in OPA.

2.32.2.2 National Organizations

2.32.2.2.1 Canadian Psychological Association

CPA was created by 38 founding members in 1939. With 3000 members and 1000 student and other affiliates, it is the oldest national association. Adair et al. (1996) describe six functions provided by CPA: dissemination of original research and informed commentary by means of its three journals, quarterly newsletters, and annual meeting; accreditation of doctoral programs and internships in clinical psychology, counseling psychology, and neuropsychology; sponsorship of member benefits; development and promulgation of a code of ethics as well as several guidelines and standards of practice; advocacy of selected issues pertinent to practitioners and scientists, often in collaboration with other organizations; and attention to the subdisciplines of scientific/academic and applied psychology through formally organized sections and interest groups.

2.32.2.2.2 Council of Provincial Associations of Psychologists

The Council of Provincial Associations of Psychologists (CPAP) consists of both regulatory and societal bodies (Craig; 1993; Wand, 1990). CPAP is a federation that evolved from an advisory committee created within the CPA in 1968 (Berry, Davidson, & Gibson, 1974). It became an autonomous entity in 1983, with the CPA as an affiliate member, and was legally incorporated in 1995. Its primary purpose is to share information and resources among provincial/territorial bodies, and to facilitate national undertakings in the common interest of its member bodies. It fosters understanding, serves as a forum for debate on issues which are ultimately decided elsewhere, and ensures that provincial/territorial matters are duly considered by national organizations.

2.32.2.2.3 Canadian Register of Health Service Providers in Psychology

The establishment of the Canadian Register of Health Service Providers in Psychology (CRHSPP) in 1985 was prompted by two factors, client/patient access and the need for a national credential. In the previous decade, psychologists providing health services were increasingly frustrated in their efforts to secure enhanced access. Funding, particularly of services provided in independent practice settings, was at the source of the accessibility problem. Policymakers in both the public and private sectors increasingly stressed that they would only pursue the possibility of expanded funding once the profession had implemented a credible means of identifying and credentialing those psychologists who had the appropriate training and experience to offer health services. The legal right to practice, while a prerequisite, was an insufficient mechanism since psychologist registration across Canada is typically generic. The fact that the practice of psychology is regulated at the provincial/territorial level highlighted both the need for a national credentialing body for health service providers in psychology and the challenge of developing uniform criteria given varying regulatory standards. The historical development of CRHSPP is reviewed by Wand (1990) and Craig (1993), and the extent to which its purpose and structure were influenced by the National Register of Health Service Providers in

Psychology in the United States is described by Ritchie (1995a). Less than a decade after its establishment, Craig (1993) noted that CRHSPP is being increasingly recognized by governments, insurance companies, and quality assurance agencies.

Unlike its American counterpart, the Canadian Register's governance is determined by its corporate members, the provincial/territorial bodies of psychology, and CPA, each of which is entitled to nominate one person to its Board of Directors. CRHSPP lists more than 3000 psychologists and publishes an annual directory. Eligibility criteria for listing are based on training, experience, and statutory registration or licensure as psychologist in a province, territory, or non-Canadian jurisdiction.

CRHSPP also plays an important role in promoting the public's access to qualified health service psychologists, and it collaborates with its corporate members, other health professions in Canada, and international bodies in furthering the development of the profession. Research on issues related to the delivery of health services and continuing education complement its broader objectives. In this manner, its strategic priorities contribute to Canadian professional psychology as a major health profession (Hurley & Ritchie, 1995).

2.32.3 HISTORY AND CURRENT STATUS OF CANADA'S HEALTH-CARE SYSTEM

Canadian federalism has produced a publicly funded health-care system that is primarily under provincial/territorial control. Nonetheless, the federal government's funding role has enabled it to shape the main features of a national, publicly funded health-care system. This section traces its history, legislation, and the impact of federal funding cuts. It concludes by noting that the mix of private and public financing of the Canadian system often is not well understood.

2.32.3.1 The Broader Context

Canada's health-care system has been the object of much domestic and external scrutiny since the mid-1980s. In the early 1990s, the prospect of health-care reform in the USA generated substantial interest in the Canadian system (e.g., Adams, 1994; Haislmaier, 1992), including mental health issues (e.g., Freeman, 1994; Torrey, Bigelow, & Sladen-Dew, 1993) and factors pertinent to psychological practice (e.g., Wedding, Ritchie, Kitchen, & Baner, 1993). Some assessments have been more critical (e.g., Danzon, 1992; Enthoven, 1990), while others have been more positive (e.g., Barer & Evans, 1992). Similar to other industrialized nations which had developed a substantial publicly funded health-care system, Canada experienced strong internal pressures to embark on its own reforms. In the short-term, this was driven largely by immediate fiscal objectives, especially that of reducing the level of public debt. Longer term perspectives, however, included concern about the sustainability of a publicly funded universal health-care system, particularly in the context of an increasingly aged population.

From an international vantage point, the creation of the UK National Health Service in 1948 is often regarded as a major benchmark in publicly funded health care. Actually, the forerunner of the modern era dates back to 1883, when the Social Sickness Fund was established in Germany. Before the close of the nineteenth century, variations were implemented in Belgium (1894) and France (1898). Luxembourg followed in 1901. Greece, Ireland, Italy, the Netherlands, Portugal, and the UK all had a form of mandatory health insurance prior to World War II. The UK National Health Service, however, introduced universality, central financing, and public administration as features which would be adopted two decades later in Canada.

2.32.3.2 Evolution of Canada's Health-care System

To appreciate the status of the Canadian health-care system as well as to understand psychology's place within it requires some knowledge of how Canada's health-care system evolved. Canada is characterized by a largely confederal system in which substantial powers are held by the constituent provinces. Although executive federalism, exercised by the federal government, has increased greatly since World War II, Canada remains one of the most decentralized federations in the world. Canada's constitutional regime has been the object of continuing intense debate within Canada.

To understand the politics and policies which influence the nature of Canada's health-care system, it is essential to know that the administration of health care is a provincial responsibility under the Canadian constitution. The federal government, however, is unfettered in its authority (known as the federal spending power) to disburse money. Hence, the Canadian federal government can make funds available to the provinces for health care (or other areas within provincial responsibility such as welfare and various social assistance programs). In doing so, it can also set conditions for the use of these funds, notwithstanding that it has no authority to administer or deliver the actual services. The only exception to this constraint applies to persons in the direct employ of the federal government (e.g., members of the armed forces) or whom the constitution has placed under exclusive federal responsibility (e.g., aboriginal Canadians living on federal reservations).

In practice, nationwide programs and national standards have developed in Canada only when the federal government has made it attractive financially for the provinces to agree implicitly to relinquish some of their autonomy. Nonetheless, the provinces always retain regulatory control for areas within their constitutional jurisdiction. Hence they can, and sometimes do, prevent institutions (e.g., hospitals) under their authority from receiving federal funds. To avoid such stalemates, Canada has evolved a form of cooperative federalism whereby the federal and provincial governments typically establish formal agreements concerning the use of federal funds in areas of provincial jurisdiction. An important feature of such agreements is that the funds are typically transferred directly to the provincial governments. These funds may be conditional (i.e., subject to meeting established criteria) or unconditional. The federal government's financial participation in health care has led to the transfer of federal funds to the provinces/territories subject to more specific conditions than in any other area of federal/provincial transfer (e.g., education).

Deber (1992) summarized the early history of the federal government's involvement in health and the initial federal-provincial arrangements which preceded the current system. The federal parliament first investigated and reported on sickness insurance in 1928. In 1935, it made its first legislative attempt to mandate the collection of information on health insurance plans, as part of a broader employment and social insurance act which subsequently was found to be unconstitutional. A health insurance bill was drafted during World War II, and the federal government offered to contribute federal funds toward a comprehensive health insurance plan as part of its Reconstruction proposal to the provinces. A conference was convened to address the Reconstruction proposal, but it could not agree on the fiscal elements of the social security proposals of which health was a part.

The federal government resorted to its spending power in 1948 to fund general health grants. However, some provinces also chose to proceed on their own, especially in establishing hospital insurance plans. Health insurance returned actively to the agenda of the annual Conference of First Ministers (which brings together the federal Prime Minister and their provincial counterparts) in 1955. This culminated in the first major federal health legislation in the modern era, the Hospital Insurance and Diagnostic Services Act (HIDS), which was implemented in 1958. Consistent with the constitution, administration of services remained under the direct or regulatory control of the provinces but receipt of federal funds was made contingent on meeting specified conditions. Eligible services had to meet tests of comprehensiveness (linked to the notion of "medically necessary"), portability, public administration, and universality. Imprecise definitions (especially of "medically necessary," a problem for the interpretation and implementation of all subsequent federal-provincial health funding arrangements), were a feature of the HIDS. Nonetheless, it marked a turning point in moving toward a national health-care system.

2.32.3.3 Cooperative Federalism in Action

The zenith of cooperative federalism regarding a national health-care system (and arguably regarding any federal-provincial matter) was reached in 1965–66 with the passage of the National Medical Care Insurance Act (MCA) which commonly came to be known as "Medicare." It received the support of all provinces and was implemented in 1968. It retained the four criteria of the HIDS but substantially expanded the range of services covered to include virtually all services provided by physicians regardless of setting (inpatient or office based). Problems of interpretation and implementation remained.

Although provinces varied in the flexibility or rigidity of the options offered to physicians for participation in the Medicare system, the outcomes were similar across the country. Overwhelmingly, physicians joined the system. Soon, 98% of all physician services were reimbursed through the various provincial plans set up under the provisions envisioned by the federal legislation, a level which has remained steady since the 1960s, growing to 99% by 1994 (National Forum on Health, 1997). Hospital services also remained largely covered by the public system, varying between 90 and 94% of all costs from the 1970s (Federal, Provincial, and Territorial Advisory Committee on Population Health, 1996).

Other professional services were funded differently. In this respect, psychologists are situated similarly to most health providers other than physicians. Inpatient and outpatient services provided within or through public facilities are covered, although the facilities and the provincial/territorial governments that fund them have full discretion on which nonphysician services they will cover. Furthermore, unlike physicians, other health professionals including psychologists have not been reimbursed through the public purse for community services delivered in their private offices. These have been funded through a range of private mechanisms including extended health plans underwritten by insurance companies.

The last major piece of federal legislation in this area, the Canada Health Act (CHA), was passed in 1984. It was essentially similar to the MCA which it replaced. Its major purpose was to strengthen the enforcement provisions available to the federal government with respect to the five principles set out in the legislation. The four basic historic criteria were retained as well as the more precise definition of accessibility. The CHA is the current legislative cornerstone of the national health-care system.

In the two decades between the MCA and the CHA, important changes occurred in the nature of the federal government's financial participation in health care. It shifted from an open-ended 50–50 shared-cost formula linked to provincial spending to a complex system of cash and tax transfers called Established Programs Financing Arrangements (EPF) introduced in 1977. In principle, two-thirds of this federal-provincial transfer were flagged for health and one-third for postsecondary education.

In the mid-1980s, the federal government introduced increasingly stringent measures to address an escalating level of public debt. These arbitrary measures included a dramatic reduction in the transfers to the provinces under the provisions of the EPF. In concert with the federal government's earlier decision to constrain provincial discretion in the allocation of federal funds earmarked for health when it adopted the CHA, the progressive decrease in the transfer of federal funds has also yielded recurrent discord in federal-provincial relations. The impact is partly reflected in the decrease in gross domestic product (GDP) attributable to health expenditures. After rising from 7.4% in 1971 to more than 10% in the early 1990s, the proportion spent on health declined to 9.5% in 1995 and is projected to decrease a bit further. This proportion is comparable to that spent in several other Organization for Economic Co-operation and Development (OECD) countries (e.g., Austria, France, Germany), but significantly less than that spent in the USA, where it has risen from 7.6% to more than 14% of GDP in the same 25 years. Given that the provinces are the direct payers of facilities and professionals (largely physicians) reimbursed by the public system, it is noteworthy that health accounted for 28.7% of total provincial/territorial government expenditures in 1976 compared to 31.2% in 1996 (Federal, Provincial, and Territorial Advisory Committee on Population Health, 1996; National Forum on Health, 1997; Thomson, 1996).

In 1995, the federal government introduced a new program, the Canada Health and Social Transfer (CHST), which integrated several previously distinct federal-provincial transfer programs into a single system. The decline in federal cash contributions has continued. However, as a function of growing political pressure and the success of its general deficit reduction policies, the federal government has committed itself to maintaining a specified minimum level of support through the CHST for a five-year period. There is little doubt that confidence in the national health-care system has been shaken, but the public's support for the principles on which it was built remains high. Indeed, the political importance of Canada's health-care system was illustrated by the 1997 federal election. Health care was a priority for all five major political parties, reflecting the salience of this issue for Canadian voters. The incumbent government was re-elected in part on its expressed willingness to make a greater commitment to stable health-care funding, including a guaranteed higher minimum level of cash transfers to the provinces/territories.

2.32.3.4 A Public–Private Mixed Model of Health-care Financing

Outside the country, the public–private blend of Canada's health-care financing is often poorly understood. Notwithstanding the generally broad nature of the public component, the Canadian health-care system functions as a mixed economy. Even the publicly funded system operates with a certain duality, since most physicians are reimbursed on a fee-for-service basis for activities provided in their private offices. This led Stoddart (1987) to observe that the Canadian system is characterized by public financing with private management.

Given the decline in public funding described above, it is not surprising to find a trend toward a greater private share of the total health care dollar. The 76%:24% public–private ratio of 1975 shifted to 72%:28% by 1994. With physician services and hospital care largely covered by the public sector (99 and 90%, respectively), private funding is concentrated on prescription drugs and the noninstitutional care provided by most other regulated health professionals (68 and 86%, respectively). To put these numbers into perspective, total health expenditures in Canada were $72 billion in 1994, or $2010 per capita, third highest among OECD countries (National Forum on Health, 1997; OECD, 1996).

The Report on the Health of Canadians (Federal, Provincial, and Territorial Advisory Committee on Population Health, 1996) concluded that Canada generally benefits from a standard of health which is among the best in the world on most indicators (e.g., life expectancy, infant mortality). From the perspective of psychological factors, it is interesting to note that indicators such as quality of life, well-being, impact of health problems on everyday life, as well as measures of mental, social, and emotional health, have been added to traditional indicators of Canadians' health status. This shift underscores the importance increasingly accorded in Canada to psychological and social variables, not only in measuring health, but in setting health policy.

2.32.4 HEALTH-CARE POLICY AND FINANCING IN RELATION TO PSYCHOLOGY

Traditionally, the services of private practice psychologists have not been covered by Medicare, and Canadian health-care policy has been rarely explicit in addressing psychological services. However, the regular salaries of most providers of psychological services are paid from public funds. Alternative public and private methods for the payment of psychologists have been actively considered and promoted by organized psychology since the 1970s.

2.32.4.1 Psychology and Health-care Policy

Canadian health-care policy evolved primarily according to a medical model of health care. Within this model, from the origin of universal-access Medicare, the provision of psychological services was associated with mental health (psychiatric) services. Traditionally, this meant that the services of private practice psychologists were not covered by Medicare. Thus, the vast majority of psychological services providers in Canada have worked as publicly funded full-time salaried employees of provincial/territorial or federal agencies such as general hospitals, psychiatric hospitals, school boards, the military, correctional facilities, and mental health clinics. Private practitioners, working primarily in the large urban centers, have been paid directly by their clients/patients on a fee-for-service basis (Ritchie, Wilson et al., 1988).

Varied psychological services are offered in Canada (Martin, Ritchie, & Sabourin, 1988). Consistent with psychology's emergence as a major health profession, health services represent the largest concentration, in such areas as health psychology (Hearn & Evans, 1993), clinical psychology (Hunsley & Lefebvre, 1990), counseling psychology (Hiebert & Uhlemann, 1993), and neuropsychology (Fuerst & Rourke, 1995). These services are offered in a wide range of settings and characterized by considerable diversity. Focusing only on general hospitals, Hearn and Evans (1993) identified 65 areas of service provided by psychologists. The traditional distinctions among clinical, counseling, and health psychology are being increasingly incorporated into the broader designation of health service psychology (Adair et al., 1996). Cognitive-behavioral and behavioral approaches are the most prevalent among a comprehensive range of theoretical orientations (Hunsley & Lefebvre, 1990; Warner, 1991).

During the 1960s, limited third-party coverage for psychological services appeared in private health insurance plans, usually as an extended benefit. Starting in the 1970s, clinical psychology broadened its scope as a health service profession, a process which has continued to the 1990s, and, although psychological services often remain associated with mental health, psychologists are broadly defined healthcare providers in the Canadian health-care system. With this change in identity, psychologists desire increasingly to be funded in the same manner as other health professionals.

2.32.4.2 Psychology and Health-care Financing

A basic question about the public financing of psychological services is: Why were psychologists not included in Medicare on a basis comparable to physicians? Inclusion of psychologists in Medicare was considered during the 1965–68 development period, but the profession itself declined to pursue such inclusion. Few psychologists shared the view prevailing among physicians that government intervention, if at all, would be limited to the disabled and those on welfare. Professional psychology's provincially based leaders focused on the fact that there were relatively few professional psychologists in Canada at the time, and were concerned about the likelihood that initial inclusion might be limited to diagnostic services.

This failure to respond affirmatively to the opportunity for inclusion in Canada's first national healthcare system has bewildered and dismayed subsequent generations of psychologists. In retrospect, the decision is perhaps best understood in terms of three factors characterizing Canadian clinical psychology in the mid-1960s. First of these was the prevailing emphasis in Canadian clinical psychology on institutionally based public service as opposed to the private practice solo-office model espoused by most physicians. Second, and equally important, was the desire to see clinical psychologists legitimized as comprehensive practitioners. In the previous 20 years, psychologists had faced and increasingly overcome obstacles to move out of the "tester" role in order to assume broader clinical responsibilities, especially as psychotherapists. There was a fear that limiting Medicare inclusion to the diagnostic services provided by psychologists might make it more difficult to consolidate their role as treatment providers. Finally, at the national level, the issue was essentially irrelevant to CPA, given its decision two decades earlier not to support the emergence of psychology as a profession. If anything, Medicare inclusion was inimical to CPA's commitment to maintain psychology exclusively as a scientific discipline without professional aspirations. Hence, there was no national effort either to seek inclusion in Medicare as a goal in itself or within a framework that would secure coverage for both diagnostic and treatment services. Such a strategy would emerge only more than a decade later, by which time provincial governments were wary of adding new providers.

As a result, among the peculiarities of the Canadian system is the reimbursement of "psychotherapy" provided by general practice physicians (many of whom have virtually no training in this field) in their private offices, while similarly situated but well-trained private practice psychologists are ineligible for Medicare reimbursement. This is an excellent illustration of the implication of funding providers and facilities rather than services, something which is increasingly regarded as a flaw in Canada's publicly funded health-care system.

Canadian health-care policy has not been explicit in addressing psychological services, except under the rubrics of mental health and some specialized health services. The absence of broad inclusion in provincial/territorial government funding mechanisms has significantly limited the public's access to primary care services provided by psychologists. Since the late 1980s, downsizing in hospitals and other publicly funded institutions has resulted in a substantial reduction in the number of salaried psychologist positions, further limiting the public's access to psychologists, even for tertiary care. However, the public funding of all health-care services, including those provided by psychologists, is in transition. As discussed below, this situation presents opportunities as well as risks to health service psychology.

Given this context, it is important to articulate the key sources and methods of payment on which Canadian psychologists are most likely to rely in future years (Ritchie, Wilson et al., 1988). The sources of payment are either suppliers or users of psychological services. Suppliers are either private or public agencies, ranging from private clinics to government administered universal health-care plans. The users may be individuals, groups, agencies, corporations, or governments.

Several methods of payment commonly used by professionals are available to psychologists. Ritchie, Wilson, et al. (1988) identified 13 types of payment and 12 generic sources of payment actually or potentially available to Canadian psychologists. The vast majority of psychologists in Canada work in regular salaried positions. In large organizations, their salaries are typically within negotiated scales and include a fringe-benefits package. A significant proportion of salaried psychologists earn additional income from part-time private practice. Since the mid-1980s there have been increasing numbers of psychologists engaging in full-time private practice. Greater reliance on alternative methods of payment is required due to the negative influence of reduced federal transfer payments on the numbers and stability of salaried positions. In addition to government sponsored services, the actual or potential sources of funding are the users themselves, organized groups (e.g., employees, cooperatives), agencies (e.g, schools, clinics, hospitals), and businesses or corporations. Payment modalities include traditional fee-for-service, sessional rates, contracts, *per diem* consultations, retainers, and capitation.

2.32.5 HEALTH-CARE REFORM AND ITS IMPLICATIONS FOR PSYCHOLOGY

2.32.5.1 Elements of a Renewed, Publicly Funded Health-care System

The rapid pace of health-care reform will continue into the twenty-first century. The policy elements which will shape Canada's health-care system from 1997 to 2020 are increasingly clear. They are well captured in the final report of the National Forum on Health (1997), commissioned and chaired by the federal Prime Minister. Future health policy will be driven by a greater emphasis on a systems orientation and by fiscal sustainability. As a result, there will be more focus on defining the services to be funded rather than on simply funding providers. Given the traditional strong emphasis on funding physicians, this change potentially allows for the emergence of a larger number of health service providers, especially in primary care. Organized psychology in Canada is working vigorously to ensure the inclusion of psychologists in a reformed primary care system, discussed further below.

Although health services may become more broadly inclusive, funding will not be open-ended and is likely to be increasingly population-based. Variations on capitation as a basic funding mechanism are under renewed consideration for both public and private sector funding. In the public sector, Canada will almost certainly remain a "single payer" system. Evidence-based decision making is regarded as a key element in making the future health-care system appropriate to meeting health needs and in controlling costs.

The transformation of knowledge into action is essential to the functioning of such a system. Health service psychologists have an uncommon advantage relative to other health professionals. They have not only the capacity to be sophisticated consumers of advanced knowledge, they are also specifically trained to generate scientifically sound data. An implication for graduate education is that applied research skills will be especially important to the future marketability of health service psychologists.

The federal and most provincial/territorial governments have achieved their essential deficit reduction targets after introducing sufficient measures to reduce the public debt in the mid-1980s. Although there is no prospect of a return to large-scale public spending, developments indicate a restabilization of public sector health-care funding. The shift toward greater privatization of health care is unlikely to exceed a 70%:30% public–private ratio in the foreseeable future. Organized psychology will sustain its efforts for enhanced coverage of psychological services in both sectors. In the public sector, efforts will likely concentrate on primary care reform. In addition, focused opportunities such as that afforded by publicly administered "no-fault" auto insurance, with access to psychological services as a benefit, will continue to be pursued in the provinces with such insurance schemes.

2.32.5.2 Private Sector Initiatives

Organized psychology's private sector initiatives are concentrating on the traditional extended health and disability plans of the insurance industry, focusing on cost offsets associated with timely use of psychological care. American-style "managed care" has not been a prominent aspect of private sector thirdparty coverage in Canada, but elements of it have begun to emerge. Cognizant of the experience of American colleagues, there is considerable interest in enhancing the role which consumers and providers can play in determining the characteristics of such plans. OPA, with the active support of CRHSPP, is working on a provider-driven plan that would potentially encompass all nonphysician health professionals authorized by statute to practice autonomously. CPAP has expressed strong interest in the possibility of such a proposal being developed as a national plan.

2.32.5.3 Globalization

The reduction of domestic and international trade barriers brought about by the AIT and the North American Free Trade Agreement (NAFTA), respectively, is emerging as a previously unanticipated influence on the evolution of health care. Considerable concern was expressed when Canada and the United States established the Free Trade Agreement in the late 1980s, an agreement that was superseded by the NAFTA, of which Mexico is also a partner. In the short term, there has been no discernible impact on health-care delivery in any of the three countries. In part, this was due to the strong intervention of the health professions in Canada, and to a more limited degree in the United States, which resulted in each NAFTA country remaining unfettered to maintain its established mechanisms for regulating health-care and health professionals. However, both NAFTA and the AIT are likely to have an impact on the future mobility of health professionals. Mobility has emerged as a central topic for organized psychology in Canada, the United States, and Mexico.

The impact of a world economy characterized by the greater globalization of national and regional economies cannot be predicted with any certainty for psychology and other healthcare professions. Among the implications for health service psychology in Canada, none will present greater challenges than the impetus toward competency-based credentialing. In Canada, medicine and nursing have already devoted substantial resources to this issue, and several other health professions (e.g., physiotherapy) are already working actively in this area. In psychology, CPA, CPAP, and CRHSPP concluded an agreement in principle to mount a multiyear, collaborative effort to address this issue. Given the diversity of regulatory standards in psychology, the task will be difficult. On the other hand, external factors, especially government policies which could ultimately impose solutions insensitive to the interests of the public or the profession, provide the incentive for the profession to achieve appropriate solutions.

2.32.5.4 Determinants of Health

Canada has been a leader in generating public policy that attends to the broader determinants of health. Since the 1970s, two federal Ministers of Health made wellness and well-being, with a population-based focus, cornerstones of major federal government initiatives (Epp, 1986; Lalonde, 1974). The importance of attending to the broader determinants of health was reiterated by the Prime Minister's National Forum on Health (1997). Specific changes in health-care delivery and social policy have yet to match the policy rhetoric, but are likely to be incorporated in the reforms into the twenty-first century. For example, according to the Report on the Health of Canadians (1996), women did not score as well as men on measures of psychological well-being and depressions, and younger women appeared to be particularly vulnerable. The report also noted that much remains to be learned about the interpretation and application of such information. This is an opportunity virtually tailor-made for psychologists, whose knowledge and skills are well suited for the planning, implementation, and evaluation of action-oriented programs with targeted health outcomes.

2.32.5.5 Scope of Health Care

From a systems perspective, the largest and most overriding issue is the determination of what is or should be encompassed by health care. In Canada, this will be determined largely by decisions made in the public sector. Canadians expect that all essential elements of health care should be accessible within the publicly-funded system. Historically, this has been driven by a focus on physicians and hospitals as the fundamental elements of health-care delivery. Now, health-care reform is creating a shift toward greater overall emphasis on the need, appropriateness, and efficacy of health services. This is not occurring without considerable disruption and resistance.

Virtually no one believes that a return to the *status quo ante* is either achievable or desirable. In the future, a larger number of services will be provided in community settings that do not require the capital intensive investment of hospitals and large-scale facilities. However, consumers also want ready access to the range of services typically found in larger facilities. Health-policy planners want to control costs and prompt a shift toward greater emphasis on the maintenance of wellness relative to the treatment of disease and injury. Canadians remain strongly committed to the five core principles on which Medicare is based (accessibility, comprehensiveness, portability, public administration, universality) but are increasingly open-minded about the possibility of changing health service delivery mechanisms in view of economic and other realities, provided that the core principles are respected.

2.32.6 THE FUTURE OF PSYCHOLOGY AS A HEALTH-CARE PROFESSION IN CANADA

Two foci provide the context for assessing the future of psychology as a health service profession in Canada. The recommendations of the 1994 Mississauga Conference on Professional Psychology provide a broad vision. Primary care, as an area of specific application, links psychology to the broader structural and funding reforms which are prompting significant changes in Canada's health-care delivery system.

2.32.6.1 A Global Road Map: The Mississauga Conference

An important global portrait of professional psychology's preoccupations and the means by which it seeks to secure its future is found in the report of the 1994 National Conference on Professional Psychology (Dobson & King, 1995), known as the Mississauga Conference. The conference was initiated and organized by CPA in collaboration with CRHSPP, the National Health Research Development Program (an agency of the federal government), OPA, the Quebec College of Psychologists, and CPA's own sections on Clinical Neuropsychology, Clinical Psychology, and Counseling Psychology.

The conference developed some 50 guiding principles and an equivalent number of specific action plans for training, funding, and advocacy. The conference report stressed that psychologists must respond constructively to the needs and expectations of the Canadian public, especially at a time of fiscal restraint. It urged that the profession's capacity for creativity and flexibility, while remaining faithful to its scientific rigor and service-oriented values, be mediated by its ability to develop greater cohesion as an organized profession. Although encompassing professional psychology as a whole, the outcomes of the Mississauga Conference are especially germane to the future of health service psychology.

The training of future professional psychologists generated stimulating debate. Preparing them for the expectations of the marketplace was established as a legitimate training goal. In this context, Evans (1995) predicted that graduate education in professional psychology would become more focused on entrepreneurial skills and more market-oriented. The conference participants reaffirmed the doctoral degree for entry to practice as a psychologist, but agreed that training models could vary in their relative emphasis on practice and research. Furthermore, the diversity of applied psychology in Canada prompted a call for organized opportunities to support the development of proficiencies associated with specialties, as a complement to education and training for general practice.

The Mississauga Conference legitimized psychology's status as a business, complementary to its standing as a profession (Hearn, 1995). The conference also emphasized that advocacy is anchored in the public interest and must be responsive to public input (Ritchie, 1995b). This is consistent with the view that professional psychology serves a broader purpose than the narrow perpetuation of guild-driven goals. Viewed as a global road map, the approved action plans of the Mississauga Conference will help to shape professional psychology in Canada in the early decades of the twenty-first century.

2.32.6.2 Primary Care: An Illustration of Psychology's Future as a Health Service Profession

Primary health-care reform, being advocated in Canada and elsewhere, will likely have major implications for the practice of broadly defined health service psychology. Driven by broader public policy issues, primary care reform affords psychology a renewed opportunity to offer its unique competencies to the Canadian public.

2.32.6.2.1 Primary health-care reform as a public policy issue

Primary health-care reform is increasingly advocated in Western industrialized countries. Historically, Canada's primary care system, driven by physicians reimbursed on a fee-for-service basis, has encouraged an episodic, medically oriented approach. In Canada, a reformed primary health-care model is recommended, among other reasons, as the continuing entry point into the health-care system and because it can comprise comprehensive, continuing care (Manga & Campbell, 1994). A strong emphasis on such a model of primary care is of interest to psychologists because a comprehensive primary care system has the potential for more efficient primary consultation time (Hart, 1992), continuing rather than episodic care (Manga, 1993), and multidisciplinary teamwork (Fulop & Roemer, 1982).

The reform of primary health care is already a major public policy issue across Canada. The 1995 Conference of Ministers of Health received a report, commissioned from their senior officials who administer the respective provincial/territorial health-care systems, which called for a radical reorganization of primary care and for the introduction of population-based funding (capitation). Psychology was explicitly among the health professionals envisioned for inclusion in the proposed "Primary Care Organizations" (PCOs).

Provincially, Quebec has embarked on an ambitious effort to develop "Local Community Service Centres," blending some elements of primary health care with some social services. However, psychologists have been significantly under-represented in such settings. The inclusion of psychologists in a reformed primary care system has received the most systematic attention in the province of Ontario, where the Minister of Health has set primary care reform as a priority. The health professions, among them psychology, have been asked to contribute to the reform process by describing their role in primary care, their linkages to other professions, and their sources of funding. Several professions, again including psychology, were further invited to collaborate on the development of an interdisciplinary model for the provision of primary care services. Psychology participated under the auspices of OPA, with national support from the CRHSPP. Psychology's proposal established a clear vision and mandate for psychologists in a reformed primary care delivery system (OPA, 1997). The following considerations are based on this proposal.

2.32.6.2.2 Principles for professional psychologists providing primary care

Psychology committed to the establishment of the most appropriate roles for psychological services providers based on the principles of patient choice, rational utilization, and evidence-based decision making. Observance of these principles requires all professionals providing primary care as partners to have access to each other.

Because psychology has a broad scope of practice including the authorized act of diagnosis, its services span primary and tertiary care. Nonetheless, most clinical services provided by psychologists fall within contemporary definitions of primary care. However, some of the services properly construed as primary care have been historically provided in hospitals and other tertiary care settings, and may continue to be so provided in some communities although likely on a reduced scale. Psychologists will also continue to deliver services which are clearly part of tertiary care, such as sophisticated neuropsychological diagnosis of closed head injury patients, in tertiary care settings.

2.32.6.2.3 Competencies brought by psychologists to primary care

The particular competencies that health service psychologists bring to primary care include diagnosis, consultation, treatment, design and implementation of prevention and health promotion programs, as well as applied research.

Psychologists have particular expertise as diagnosticians. In community-based health-care settings, there is a high prevalence of patients with psychological problems or disorders associated with their physical complaints. Contrary to historic practice patterns, cost-effective patient care indicates that, in such cases, psychological diagnosis should be undertaken before other, considerably more expensive, diagnostic procedures. This will be feasible only when psychologists are as readily accessible to patients as physicians and nurses, and when psychologists' community-based services are publicly funded. It is expected that psychologists would both see patients for diagnostic consultation and provide partner health professionals with consultation around relevant diagnostic questions. Where the diagnostic question is primarily psychological, psychologists would be the most effective coordinators of the diagnostic process. This would be particularly important when the level of diagnostic complexity is moderate to high.

Treatment is a second major area of direct and indirect service. In future, the emphasis will likely be on short-term, empirically-supported approaches. Group therapy will be a preferred treatment modality, coupled with timely utilization of individual, couple, or family psychotherapies. Psychologists may provide treatment directly, supervise the treatment provided by other professionals, or provide consultation to other providers concerning the planning and implementation of appropriate treatments.

Psychologists will play a leading role in the design, adaptation and refinement of large-scale community based prevention and health promotion programs. Furthermore, since health-care settings will be expected to conduct in-house applied research, the fact that psychologists are educated as applied scientists will enable them to make a substantial contribution in this area, particularly in the areas of needs assessment, outcome evaluation, program evaluation, and clinical research.

Finally, the linkages of psychologists to other health professionals are expected to be strengthened in primary care agencies. In such settings, psychologists would probably have three types of linkages with other professions. Linkages would begin with day-to-day operations. All health-care providers would work in proximity to each other, and be accessible to their fellow providers and to each other's patients. An emphasis on patient need, rather than established patterns of service delivery, would benefit the patient, promote interdisciplinary collaboration, and enhance cost-effectiveness. The key would be access to the right provider for the most appropriate service at the right time.

Coordination and communication among various health practitioners, and across community agencies and services, are essential to the care of patients presenting with multiple physical and social needs. Primary care agencies would be well placed to play a central coordinating role, with participation from psychologists and other health professionals.

Psychology-specific linkages would likely derive from the health needs and referral patterns that are central to the work of psychologists. For example, psychologists would facilitate access to psychological services in tertiary facilities, and would make direct referrals to the specialized health services of psychiatrists, neurologists, pediatricians, and others.

2.32.6.2.4 Funding for psychologists providing primary care

The absence of province-wide public funding mechanisms across Canada has been the greatest impediment to the appropriate utilization of primary care services provided by psychologists. Traditionally, psychologists have provided some primary care diagnostic and treatment services in the outpatient departments of general hospitals, but downsizing has eliminated many positions and rendered psychological services less accessible.

The shift to a capitation funding system based on formulae driven by the demographics offers potential advantages to psychologists. In particular, funding will not be limited to physician services. However, there are utilization risks which will be borne by the providers rather than by the funder (i.e., provincial/territorial governments). Hence, careful attention to the derivation of capitation funding formulae will be required. Unfortunately, psychologists and other providers have little historic experience and data upon which to draw to bolster their negotiating strength in such negotiations. Governments will also have a stake in demonstrating good faith to ensure the success of primary care agencies to maintain the credibility of primary care reform with the public. When primary care agencies are set up, practitioners who are eligible for some private sector funding for other services may be able to offer an expanded range of services through a blend of public and private funding, provided that services reasonably construed as primary care remain publicly funded.

2.32.7 CONCLUSIONS

The long-standing dichotomy between psychology as a profession and psychology as an academic discipline had a retarding effect on the development of a cohesive national strategy for the profession in Canada. The emergence of stronger provincial/territorial associations, a reversal of CPA's previous antipathy to professional psychology, the creation of the CRHSPP, successful advocacy efforts which strengthened psychology's legitimacy through legislative recognition and the exemption of psychological health services provided by CRHSPP Listees from the federal Goods and Services Tax, have all enhanced Canadian psychology's standing significantly as a major health-care profession since 1980.

Although psychological services have not been covered directly by Medicare, the vast majority of psychologists in Canada have been reimbursed from public funds as regular salaried employees. Parallel services that emerged through private sector funding have improved public access to psychological services for some segments of the population. Full-time private practice remains the fastest growing segment of professional psychology in Canada. The development of innovative funding mechanisms is being pursued by organized psychology and entrepreneurially oriented psychologists across the country. Throughout Canada, health-care psychologists offer an increasingly wide range of high-quality services. Notwithstanding a decade of significant disruption and dislocation in publicly funded health services which has affected all health-care professions, there is in the late 1990s a reasonable likelihood of stable public funding, albeit at a reduced level when compared to historic baselines. The potential inclusion of psychologists in a reformed primary health-care system offers a promising opportunity to remedy limitations on the public's access to community-based psychological services engendered by anomalies in the Medicare program since the 1970s. On balance, after a period of sustained evolution since the 1940s, the realistic prospect for Canadian health service psychologists is bright for those who are prepared to adapt to emerging opportunities.

2.33.1 INTRODUCTION

The US' health care system is undergoing unprecedented changes which will have a direct impact upon the future of professional psychology. These include: increasing acceptance of managed care, extraordinary technological advances within the computer and communications industries, drastically increasing numbers of psychologists, and the evolution of psychology into the generic health care arena. Advances in telehealth constitute major opportunities and challenges. Obtaining prescription privileges represents an entirely "new frontier." Psychology is one of the "learned professions" and should prosper if the practitioner and academic communities work collaboratively to address society's pressing needs. Is the next generation willing to become involved in the political and public policy efforts that are required?

2.33.2 PROFESSIONAL PSYCHOLOGY: ONE OF THE "LEARNED PROFESSIONS"

The USA is considered to be highly educated. Yet, the reality is that slightly less than 20% of adults possess a baccalaureate degree, and of those entering division one colleges, only half (56%) actually graduate within six years (DeLeon, Sammons, & Sexton, 1995).

Accordingly, it is contended that professional psychology, with its historical emphasis upon doctoral level training, has a truly unique and pressing societal responsibility to act as one of the "learned professions" (DeLeon & Wiggins, 1996). Society's pressing needs must be addressed affirmatively wherever psychological expertise could be deemed relevant. There is a societal obligation to work to ensure that all Americans have access to quality health care, including mental health care. There must be a collective responsiveness to the ever expanding opportunities for the psychology profession as it evolves within the nation's health care and educational arenas. Simply stated, psychologists have a responsibility to demonstrate effective leadership. As one of the "learned professions," psychologists must not "sit on our laurels" and be complacent.

Reflecting on the profession's past, psychology has an impressive history of successfully overcoming numerous obstacles to the establishment and expansion of professional practice. Psychologists are now authorized to autonomously provide psychotherapy in all states, are independently reimbursed for services rendered under nearly every federal and private health program, are routinely granted hospital privileges in the public and private sectors, and provide expert testimony in the courts (Resnick, DeLeon, & VandenBos, 1997). By 1996, 47 states had enacted psychology "freedom of choice" statutes.

The establishment of professional schools has resulted in numbers expanding beyond anyone's expectations. The current estimate being in excess of 70 000 licensed practitioners and an American Psychological Association (APA) total membership, across all categories of members, in excess of 150 000. Psychologist colleagues have been appointed to numerous positions of public trust. Approximately one third of US states have selected psychologists to direct their mental health system. Psychologists have served in numerous positions of high level federal responsibility; including in the US Congress, as Institute directors, head of the Federal Bureau of Prisons, and hospital (facility) commanders. The future should bring similar administrative and legislative recognition, not to mention broader clinical appreciation for the inherent value of the behavioral and psychological sciences throughout the delivery of quality health care (VandenBos, DeLeon, & Belar, 1991).

However, it must also be reported that some senior colleagues have begun raising serious questions about the profession's collective willingness to continue to engage in the administrative and legislative struggles that are required. It is as if the current generation of professional psychologists believes that they are entitled to a comfortable life, rather than being willing to work aggressively to obtain or maintain one. Stated slightly differently, recent graduates do not seem to appreciate the importance to their profession (and to society) of becoming personally involved in the public policy and political process. Interestingly, this phenomenon seems also to be the case within a number of the other nonphysician disciplines. It has further been observed that unlike many colleagues in the other disciplines, very few psychologists truly appreciate the long-term policy implications for practice of fostering viable clinical-training collaborative relationships (DeLeon, 1989).

2.33.3 MANAGED CARE

There can be little question that for most practitioners (and increasingly for those who are employed within academia) the 1990s can be summarized by the dreaded phrases "the advent of managed care" and the "industrialization of health care." Across the nation, many colleagues report that their incomes are being dramatically slashed. Practitioners, and particularly those in solo private practice, have become increasingly vocal in decrying the intrusion of managed care into their lives; allegations are made that the "quality of care" they are now able to provide may no longer even be within ethical boundaries; and that clinicians' complex judgments are simply not valued. In essence, many colleagues sincerely believe that efforts to curtail the costs of health care have supplanted providing necessary and quality health services. It is as if managed care companies are practicing health care, rather than administering a health care benefit (Miller, 1996).

Few would argue that there have not been unconscionable abuses under managed care. And, it is also the case that those who ultimately pay the bill have become increasingly involved in questioning what it is that they are actually receiving for their money. Many colleagues are fierce individualists; it would be an understatement to suggest that they passionately object to having anyone "overseeing" their clinical judgment. And yet, there is also a growing body of evidence which highlights that unnecessary variances exist in health care delivery, particularly in certain geographical areas (Wennberg, 1984). And, further, that credible indications continue to surface that many clinicians (regardless of discipline) always seem able to proffer "reasonable reasons" to provide services, as long as they will be reimbursed.

Notwithstanding the considerable emotional turmoil surrounding managed care expressed by numerous practitioners during the past years, the 1990s has also seen increasing numbers of psychologists working with, or being employed by, credible managed care organizations. Many report that they are very excited about their increasing ability to contribute significantly to improving their patients' overall health status, and that their practices are constantly expanding into entirely new and previously unforeseen arenas. A fundamental policy question that has been raised by the leadership of the Committee for the American Psychological Association of Graduate Students (APAGS) is: Have our training programs really kept up with the evolving changes in health care delivery? Or, is psychology instead training a generation of practitioners who will ultimately not possess the fundamental skills necessary to survive in the changing health care environment?

The practical, financial, and clinical reality is that increasing numbers of Americans are enrolling in managed care. Both the Clinton Administration and the Republican Congress continue to express great faith in the quality of care that is provided by managed care organizations. In 1996, nearly 57% of all Americans were covered by managed care, a doubling of the number from a decade ago. Nearly three-quarters of Americans covered by employer-based health insurance plans are enrolled in managed care plans, compared with only half in 1993. The Administration's Fiscal Year 1998 budget request for the Department of Health and Human Services (HHS) expressly noted that since 1993, the number of Medicare and Medicaid beneficiaries enrolled in managed care plans has experienced unprecedented growth. Focusing specifically upon the delivery of mental health care, it is estimated that 149 million people are insured through managed behavioral health firms (National Health Policy Forum, 1997). Previously enacted psychology "freedom of choice" laws will need to be amended to reflect the changing market place. The Balanced Budget Act of 1997 (P.L. 105–33) provided the states with greater flexibility to require individuals receiving Medicaid to enroll in managed care plans and specifically eliminated the previous statutory requirement that the states first needed to obtain a formal waiver from the federal government (i.e., HHS).

From a public policy perspective, it is evident that many simply do not appreciate that managed care is here, and that it is not a new conceptual entity. Managed care existed during the days of the great depression, and managed care was the cornerstone of President Nixon's health care agenda (DeLeon, Bulatao, & VandenBos, 1994; DeLeon, VandenBos, & Bulatao, 1991). The health programs of the various federal and state agencies (i.e., the Veterans Administration [VA], Indian Health Service, and Department of Defense) have always had to face the realities of providing comprehensive health care, for an identifiable patient population, within finite budgetary constraints (i.e., have been "managed"; Blanck & DeLeon, 1996). A related and equally significant fundamental health policy concept is that many psychologists are just beginning to appreciate that the delivery of psychological services extends far beyond the delivery of only mental health care *per se*; and that from a public policy perspective, psychological care is but a small subset of health care (DeLeon & VandenBos, 1991). Psychologists are health care professionals.

2.33.4 TELEHEALTH–TELEMEDICINE

2.33.4.1 Federal Developments

One of the most exciting and far reaching developments that has occurred within the health care arena since the mid-1980s has been the increased clinical applicability of computer and telecommunications technology. Historically, most Americans (and particularly practitioners) have viewed the process of receiving health care as a highly personal, one-on-one experience between the patient and practitioner (usually a physician or dentist). With the advent of the nurse practitioner and physician assistant movements during the mid-1960s (DeLeon, Kjervik, Kraut, & VandenBos, 1985), the notion and appropriateness of "physician extenders" providing care became increasingly acceptable, if not commonplace, that is, the fact that there might be someone (or something) in between the doctor–patient relationship began to seem normal. In the late 1990s, the unprecedented advances in technology which are occurring are taking this process a significant step further—the actual physical location (i.e., presence) of the practitioner is becoming almost irrelevant.

In 1994, a bipartisan, bicameral *ad hoc* Steering Committee on Telehealth and Health Care Informatics was established in the US Congress. Its objective was to allow interested members to informally explore how these technological advances might best be utilized to improve access to quality health care, particularly in rural America. It seems intuitive that the increasing sophistication and exponential growth of technology must have clinical implications for health care delivery—but exactly in what fashion has yet to be determined.

In many ways, the clinical application of telehealth–telemedicine is still in its developmental stages. Accordingly, it is pleasing to note the extent to which various governmental agencies and private organizations with health policy expertise have begun collaborating to establish a comprehensive policy framework for what might evolve. By the end of the first session of the 105th Congress (1997), impressive reports had already been issued by the Institute of Medicine (IOM, 1996), the former Office of Technology Assessment (US Congress, OTA, 1995), the General Accounting Office (GAO, 1997a), and the US Department of Commerce (1997). The federal government had established a Federal Interagency Joint Working Group on Telemedicine, which among other responsibilities has been tasked with establishing a world wide web-accessible inventory of federally-sponsored telemedicine projects. Note, as an aside, the consistent efforts by organized medicine and the Clinton Administration to utilize the policy phrase "telemedicine," notwithstanding the Congress' statutory preference for the more generic and inclusive term "telehealth."

Some of the highlights from these reports are: by the end of 1996, nearly 30% of rural hospitals were expected to use telehealth to deliver patient care; more than 40% of telehealth programs were in operation one year or less; and the most common clinical uses for telehealth were diagnostic consults, medical data transmissions, and management of chronic illnesses.

The Commerce Department report (1997) expressly addressed the potential applicability of telehealth for mental health services:

> Unlike some specialties such as cardiology, mental health telemedicine applications do not require a high degree of image specificity, thus the technology can be simpler and costs can be lower. Moreover, initial evidence indicates that telemedicine works well for group therapy as well as individual consults. (p. 19)

By the middle of the 105th Congress over 35 federal organizations, 10 state governments, and numerous private organizations had sponsored hundreds of initiatives in over 40 states. According to the Department of Commerce, over a three-year period, the Federal government alone invested more than $646 million, with different agencies developing their own unique priorities. The Library of Medicine of the National Institutes of Health was projected to be providing $42 million, targeting proposals that examined specific use of the technology in health care, whereas the HHS Office of Rural Health Policy was targeting multispecialty networks of care, stressing improving access to care in rural areas.

The Office of Rural Health Policy is the lead telehealth programmatic agency for HHS. In Fiscal Year 1996 it awarded $9.9 million in grants under one particular initiative, in which grantees were to belong to, or propose becoming members of, a network and thereby able to provide a minimum range of services. Each network was to provide a minimum of seven services, one of which was to be the stabilization of patients in emergency services. Although to date psychology has been only tangentially involved, the potential is definitely present since the office has demonstrated an explicit emphasis on encouraging multidisciplinary and community-focused care, with priority being given to projects that proposed providing care in such community-based settings as schools, assisted living facilities, individuals in the home, and so forth. That year, the Office awarded an additional $4.75 million to eight telemedicine projects under its rural health outreach grant program, as well as providing support to two major telemedicine demonstration projects in West Virginia and Iowa. Overall, between 1994 and 1997, the Office awarded approximately $36 million in telehealth funding.

2.33.4.2 Professional Issues

Some of the evolving clinical and public policy issues in telehealth that should be particularly relevant to professional psychology include: confidentiality of patient records, insurance reimbursement, interstate licensure decisions, malpractice liability, and the potential for "cookbook medicine" or requiring predetermined algorithms of care. Many of these policy issues will eventually be debated at the state level, both in the legislature and by administrative agencies. By the end of 1997, 15 states had decided to offer some telemedicine coverage under their Medicaid programs and the states of California and Louisiana had enacted legislation mandating coverage for telehealth consultation services under private insurance plans.

Health policy experts and clinicians can readily appreciate how this advancing technology might work for services that are primarily visual (or physical) in nature; that is, reading x-rays, performing dermatology consults, and transmitting medical records over long distances. For professional psychology the underlying question becomes: how can telehealth capabilities facilitate traditional psychological interventions which may not be as concrete (or physical) in nature? Computerized testing and diagnostic interviews and consultations are possible. What about providing psychotherapy? The more one gets involved, it also becomes clearer that there remains the critical issue of how to facilitate practitioner acceptance of this new technology.

Reflecting again upon the profession's training programs from a national frame of reference, the APA past-President Ron Fox has reported that there are approximately 26 identifiable telehealth programs within medical school environments, but none within psychology's training programs (personal communication, 1997). Fortunately, various elements of the APA governance (the Board of Educational Affairs, the Committee for the Advancement of Professional Practice, the Board of Professional Affairs, and the Committee on Rural Health) have begun addressing the policy and programmatic implications. The Department of Commerce report expressly referenced psychology's efforts. Telehealth is becoming a major factor in the delivery of mental health care. The *American Medical News* (1997, November 10) reported that mental health, constituting 20% of the 1996 consultations, has become telehealth's most common use.

For psychology, the fundamental issues of interstate licensure, privacy/confidentiality concerns, and patient outcome measures must be systematically addressed. Already a number of states (10 by 1997) have decided to require that telehealth practitioners possess multistate licensure. Professional nursing, however, has been considering urging their licensure boards to adopt a "driver's license" approach, under which the practitioner/consultant would only be required to be licensed in one state. Within medicine, the Federation of State Medical Boards is exploring what approach they should recommend as appropriate guidelines to their licensure boards.

The leadership of professional psychology, and in particular the leadership of its professional schools, must collectively become systematically involved in the ongoing HHS demonstrations and policy dialogues. For example, the Health Resources and Services Administration (HRSA) requested policy guidance on:

> the legal barriers to the cost-effective use of telemedicine and specific suggestions for overcoming these barriers. In particular, we seek suggestions for easing licensure barriers to physicians and other health professionals providing telemedicine services across state lines, and comments on specific alternatives, such as those recently proposed by the Federation of State Medical Boards and the Institute of Electrical and Electronics Engineers ... (R)espondents are encouraged to provide comments and suggestions on other legal issues associated with telemedicine such as liability/malpractice ... to identify the particular challenges in assuring privacy, confidentiality, and security in the conduct of telemedicine and provide suggestions for addressing those challenges. Comments will be reviewed and considered for incorporation into the final report to Congress. (*Federal Register*, August 9, 1996, p. 41 640)

We must ask ourselves: what elements of professional psychology, other than the professional schools, might become involved in the actual delivery of health care utilizing telehealth? And, thus, intimately affected by governmental decisions?

To again focus upon the federal government's role as a provider of health care and to give another perspective of the extent to which telehealth has already matured: in 1996, the health officials of the Department of Defense (DoD) testified before the Senate Appropriations Committee (US Department of Defense, 1996, S. Hrg. #104–756). The witnesses described their considerable enthusiasm for the clinical and teaching potential inherent in the technology revolution. Medical digital technology, telemedicine, advanced computer-based medical expert systems, information management—

for combat as well as for day-to-day business and clinical practice—were explicitly addressed. Allowing attending providers on board ships to transmit real-time ultrasound videos and full color images back to specialists at major treatment facilities hundreds of miles away was clearly "doable." It was noted that DoD's telehealth presence in Bosnia was extraordinary.

As we have indicated, the DoD is a major provider of health care. It administers care in 116 military hospitals and 513 clinics for a beneficiary population of over 8.3 million, with a medical budget of approximately $9.6 billion annually. In 1996/97 alone, DoD spent $48 million developing telemedicine infrastructure. What lessons can be collectively learned from military colleagues?

2.33.4.3 Federal Legislative Developments

The Kennedy–Kassebaum health insurance legislation, the Health Insurance Portability and Accountability Act of 1996 (P.L. #104–191), surfaced some very interesting policy implications for professional psychology, not the least of which was the extensive debate surrounding the possibility of enacting mental health parity legislation. The final enacted bill did not include the mental health parity provision but did recognize that advances in health care technology, and specifically telemedicine, will have a major impact upon how health care will be delivered in the future. The conference agreement

> directs the Health Care Financing Administration (HCFA) to complete its ongoing study of Medicare reimbursement of all telemedicine services and submit a report to Congress on reimbursement of telemedicine services by March 1, 1997. The report would . . . include an analysis of the cost of services provided via telemedicine, and include a proposal for Medicare reimbursement of telemedicine services. (H. Conf. Rpt. #104–736, p. 235)

The Balanced Budget Act of 1997 (P.L. 105–33) was subsequently enacted and took the next step by requiring the Secretary of HHS to continue the Department's three-year demonstration project under which Medicare will pay for telemedicine services at 57 Medicare-certified facilities and to make Part B payments under Medicare for telehealth "professional consultation" services available by no later than January 1, 1999. Interestingly, this same legislation also substantially modified the Graduate Medical Education (GME) program (which will be addressed in more depth later in the chapter) in ways which could have a major impact upon psychology as a health profession. Historically, the GME program has stressed hospital based services and has been physician dominated. The Budget Act expanded direct medical education payments to entities that were previously not eligible (and where psychologists are increasingly being employed), specifically to federally qualified health centers, rural health centers, and Medicare + Choice organizations. Most importantly for psychology, the conference report expressly "urges the Secretary to include physician assistants and psychologists under (the allied health) authority" (H. Conf. Rpt. #105–217, p. 822) for determining reimbursement.

During the conference deliberations on the Fiscal Year 1998 Appropriations bill for the Department of Defense (P.L.105–56, 1997), specific language was also included focusing upon telehealth:

> The conferees agree that pursuant to the GAO report "Telemedicine: Federal Strategy is Needed to Guide Investments," DoD Health Affairs should contract with an outside organization, which has previously demonstrated the ability to assess and plan strategic telehealth initiatives, to enumerate current telehealth efforts and recommend coordination activities among the tri-services to prevent duplication and enhance "dual use" telecommunications for health care delivery, education, and related public sector applications. This assessment should also include the worldwide computer-based patient record as a necessary component of telehealth. The resulting report and recommendations shall be provided to the congressional defense committees by April 1, 1998. (P. L. 105–56, 1997, H. Conf. Rpt. #105–265, p. 139)

Clearly major advances are evolving in telehealth within the federal sector. To cite another example, the Senate reports accompanying the DoD and VA appropriations bills for Fiscal Year 1998 also formally recognized this technology's potential for upgrading VA nursing staff professional skills.

> VA/DoD distance learning pilot project. The Committee encourages the DoD to continue the VA/DoD distance learning pilot project to transition clinical nurse specialists to the role of nurse practitioners. This collaborative program with the USUHS Graduate School of Nursing will increase the number of primary care providers. (Sen. Rpt. 105–45, p. 149)

And,

> The Committee encourages VA to continue the VA/DoD Distance Learning Pilot Program to transition clinical nurse specialists to the role of nurse practitioners. This collaborative program

> with the Uniformed Services University of the Health Sciences Graduate School of Nursing will add to the number of primary care providers required to care for the projected increase in the numbers of aging and female veterans. (FY 1998 Departments of Veterans Affairs, 1997, Sen. Rpt. #105–53, p. 16)

We would rhetorically ask: are VA psychologists involved in these activities?

2.33.5 PRESCRIPTION PRIVILEGES

The move towards prescriptive authority (DeLeon, Fox, & Graham, 1991; DeLeon, Sammons, & Sexton, 1995) takes place in the context of two major shifts in health care provision and training. The first of these is that organized medicine is gradually losing its monopoly on the provision of health care services. Other health care specialties—such as advanced practice nursing, podiatry, and optometry—are moving into fields which had previously been the sole purview of the physician. In the USA, though not the case globally, control of the prescription pad has long been the *sine qua non* of medicine. American medicine has found that control of prescriptive authority has proven to be an astonishingly potent political tool, and, since the beginning of the twentieth century, considerable effort has been expended by physicians to establish a relative monopoly on this function. Surrendering this authority, which is an emblematic step in the gradual dissolution of medicine's hegemony in health care provision, is the subtext which underlies the opposition by psychiatry and other branches of organized medicine to the acquisition of prescriptive authority by psychologists.

The data illustrating this shift are dramatic. An extraordinary illustration of this trend is revealed by the fact that the number of prescriptions written by nonphysician prescribers more than doubled between 1992 and 1996. In 1992, 0.22% of all prescriptions were written by nurse practitioners or physician assistants; in 1996, this figure was 0.57%. Though still small in comparison to the overall numbers of prescriptions written, this percentage represents over one million prescriptions per month (*American Medical News*, 1996, June 17). Since July, 1995, the Drug Enforcement Administration (DEA) has issued controlled substance prescription numbers to nurse practitioners and physician assistants.

These numbers have been driven by remarkable legislative successes by the various professional groups. In particular, those of advanced practice nurses (APNs) have demonstrated the changing scope of health care provision. In 1975, North Carolina became the first state to provide nursing with prescriptive authority. By 1996, APNs had some form of prescriptive authority in all states except Illinois. In 19 states, they could prescribe from formularies including controlled substances completely independent of physician involvement, a figure which had almost doubled from two years previously, when APNs could prescribe independently in only 11 states. In 1997 it was estimated that there are approximately 75 000 APNs throughout the nation. Optometrists and podiatrists possess prescriptive authority in all states (except the District of Columbia, for optometry). Physician assistants and pharmacists have acquired more limited forms of prescriptive authority, but at a rate which is quickly expanding. In the case of podiatry and optometry, these privileges are granted without physician oversight, and the degree of latitude afforded physician assistants and pharmacists has increased significantly. In the US Army there is a program for physical therapists, ongoing for more than two decades, under which they are granted prescriptive authority in the course of treating neuromuscular complaints (Benson, Schreck, Underwood, & Greathouse, 1995).

Although the medical press frequently implies that nonphysician prescribers imperil patients' well-being (i.e., are "public health hazards"), data have long been extant which demonstrate that nonphysician health care providers prescribe psychotropics at least as well as their medically trained counterparts. Studies in the 1970s demonstrated that nonmedically trained mental health providers, armed only with knowledge acquired during weekly seminars, did not differ from psychiatrists in their prescribing patterns (Platman, Dorgan, & Gerhardt, 1976). In the state of California, over a million patients were seen by nonphysician prescribers with no adverse consequences (State of California, 1982). Interestingly, less than 20% of all psychotropic medications are ordered by psychiatrists.

In addition to the results of demonstration projects and similar efforts, overall differences in safe practices between physicians and nonphysicians can be inferred by using the frequency of successful malpractice actions against both groups. Here, the extant data speaks clearly in favor of the argument that nonphysicians prescribe safely. In general, nonphysician groups are usually more successful than their physician counterparts at avoiding completed malpractice actions. For example, in a study of lawsuits related to failures to diagnose heart attacks, it was discovered that physician extenders were successfully sued least often among a varied group of medical specialties (including cardiologists and general practitioners), accounting for only four of 495 claims in the reporting period (Flannery, 1997).

Figures for prescribing psychologists are, of course, not available, but tangential evidence suggests parallel experiences for psychologists. A 13-year history of malpractice actions against psychologists in California indicated a total absence of successful claims for failure to diagnose medical conditions in patients seen by psychologists (Dorken, 1990). From these data one could reasonably infer that malpractice actions would not be a significant concern for those who prescribed. Further oblique support for this position comes from another interesting study which found that psychologists were as good as general physicians, and slightly (but not significantly) better than a small group of psychiatrists, in detecting Axis III conditions masquerading as Axis I problems (Sanchez & Kohn, 1991).

Patient acceptability of nonphysician prescribers has been good, particularly within organized systems of care. In England, nurses were granted prescriptive authority in 1994. A survey of patients after this change suggested that most patients were comfortable with this new arrangement. The principal benefits seen were that patients no longer had to visit two providers in order to get a prescription, that time was saved, and that patients could get medications from providers with whom they had previously established trusting relationships. No patients expressed opposition to the idea of nurse prescribing (Luker, Austin, Hogg, Ferguson, & Smith, 1997).

Among psychologists, the Psychopharmacology Demonstration Program (PDP) established under the auspices of the Department of Defense has provided a unique laboratory for experimentation in curriculum development for prescribing psychologists (Sammons & Brown, 1997). The program was established during Congressional deliberations on the Fiscal Year 1989 DoD Appropriations bill (P.L. 100–463, 1988) and has now graduated 10 Fellows who are privileged to prescribe at their military facilities. There have been several independent evaluations of the highly controversial program which have confirmed that the Fellows provide high-quality health care. There is disagreement, however, as to whether the program has been cost-effective (GAO, 1997b; Jones, Cohen, Munsat, Dorris, & Berson, 1996).

The second major shift is more specific to organized psychiatry. It is a subset of the first; that is, reflecting the gradual reduction in power of organized medicine. From our vantage point, it is clear that there is growing recognition that psychiatry as a profession has imperiled its existence by excessive reliance on biological models of psychopathology and biological interventions. And perhaps even more significant in the long run, psychiatry has not been able to attract a critical mass of American medical school graduates into its residencies.

A number of psychiatrists are now beginning to understand that the future of their profession as a discipline may depend to a great extent on its ability to combine psychological and pharmacological approaches to treatment. Unfortunately, a history of excessive reliance on ideologically grounded disciplines (first Freudian psychoanalysis, and later psychopharmacology), has limited the clinical evolution of psychiatry. In our judgement, psychology is a much more heterogeneously grounded discipline, and the variety of subdisciplines which make up the field have allowed us to sidestep the trap of falling into a single treatment modality. Nonetheless, it is important that psychologists recognize that, in order to prosper, they must be open to embracing ideologies and methodologies that had previously been regarded as outside their scope of practice. They must be careful not to emulate the mistakes of physician colleagues, who have found that reliance on unimodal treatment strategies quickly leads to obsolescence. Instead, they must develop and utilize the most appropriate investigatory techniques to determine which treatments, and in which combinations, will optimize the science and clinical practice of psychology.

2.33.5.1 Fewer Prescribers, Greater Challenges—Rising Needs

By the year 2020, psychological and behavioral disorders, such as major depression, bipolar disorder, panic disorder, schizophrenia, and alcoholism will have surpassed all but a very few other causes of worldwide morbidity and mortality. On a global level, unipolar major depression is projected to represent the second most significant contributor to disability adjusted life years, and neuropsychiatric conditions in general will contribute 10.5% to disability adjusted life years (Murray & Lopez, 1997). Again, a rhetorical question: what are the training programs doing to target these populations?

2.33.5.2 The Challenge of Psychiatric Residency Training

In 1994, only 3.2% of all US medical school graduates entered a psychiatric residency, the lowest number since 1929 (Sierles & Taylor, 1995). At the same time, the number of international medical graduates (IMGs) entering US residencies has escalated exponentially, and has increased 64.7% since 1990 (Peterson et al., 1997). The influx of IMGs who enter US residencies and then stay to practice medicine (as the majority of IMGs do) is not unique to psychiatry. Nationwide, 25.2% of all medical residency slots are filled by IMGs, but the problem is particularly acute in psychiatry where nearly half (41.8%–49.5%) of all US psychiatry residency programs are dependent on IMGs—that is, over 50% of their first year residents are IMGs (Whitcomb & Miller, 1995). It has been estimated that if Congress merely adopted the recommendations of organized medicine as to how to limit the percentage of GME payments currently going to international medical graduates, psychiatry would experience a 40% reduction of its residency slots the first year alone.

It has been noted that the oft-cited rationale for utilizing IMGs (i.e., that they would provide more services to indigent citizens) was not found to be true, with only a minority of IMGs being engaged in treating the poor and traditionally underserved. Could it be that the high percentages of IMGs in US psychiatry may be a factor in the astonishing utilization of psychotropic medications by their specialty? It has been reported that the percentage of psychiatrists' patients receiving medications rose from 27% in 1975 to 54.5% in 1988. Similar analysis of data from 1988 and 1989 indicated that 61.7% of all psychiatric patients received medication, and that IMGs were disproportionately represented in that group of psychiatrists defined as "high medication practice" (Olfson, Pincus, & Sabshin, 1994). As others have demonstrated, the percentage of psychiatric patients receiving medication continues to climb, with over 90% of patients receiving at least one drug in a 1996 survey of psychiatrists (West, Zarin, & Pincus, 1997).

During the DoD psychopharmacology training program, the Fellows became acutely aware of the relevance of their psychological training to the complex issues surrounding utilization of psychotropic medications. There are a number of prescribing areas in which psychology should be more actively involved; particularly, in asking relevant clinical utilization questions. Gender-specific training in clinical psychopharmacology is an open and challenging field. From a pharmacoepidemiological perspective, differential rates of prescribing for men and women are well recorded. Women are more likely than men to be prescribed psychotropic drugs, and this difference is not entirely explainable by generally higher rates of diagnosis of mental distress in women. In particular, elderly women are more likely than any other segment of the patient population to receive psychotropics. The factors which contribute to these discrepancies are less well understood. Is gender of the patient the sole determinant of differential rates of prescribing? This seems unlikely. It is more likely that an interaction exists between the gender of the prescriber and gender of the patient which can further explain such differences.

Another clinical issue which requires elucidation is the persistence of high risk prescribing patterns, despite the availability of data suggesting safer clinical strategies. It has been noted that this is an especially significant issue for elderly females, who receive disproportionate shares of psychotropic medication. On a more preclinical level, gender specific physiological functions, such as the effects of pregnancy, lactation, menopause, and estrogen levels on both the production of mental disorders and the pharmacokinetic and pharmacodynamic properties of psychotropic drugs, still await extensive investigation.

2.33.5.3 Towards More Rational Prescribing Practices

It is reasonably clear that a medical degree and completion of a psychiatric residency *per se* is not the prime determinant of best prescribing practice of psychotropics. Thus, a question that begs investigation is to clarify the essential components of the knowledge base which underlies skillful prescribing, and perhaps more importantly, what components of education (didactic and clinical) are necessary to allow providers to distinguish when a patient will be more responsive to medication or nonallopathic therapies.

Since the Second World War, the pharmacopoeia for mental disorders has expanded exponentially. The development of effective pharmacological treatments for many forms of mental distress has revolutionized mental health care and eased the suffering of untold numbers of patients. But in spite of advances in drug treatments and greater understanding of neurochemical processes in mental illness, collective insight into the mechanisms of action of almost all psychotropic drugs remains rudimentary. And, decades of clinical experience notwithstanding, there do not as yet exist universally defined, science-based criteria to guide the clinician in the selection and use of specific drugs for the treatment of any mental disorder.

These gaps in knowledge can partly be ascribed to the incomplete maturation of the mental health field. Additionally, a history of what must be considered fairly "shaky research" methods has led to questions regarding generalizability of clinical trials (Healy, 1990; Kraemer, 1995). Certain issues, such as the existence of a large placebo effect in psychotropic drug studies, continue to bedevil researchers in the field. The subject of generalizability has aroused considerable recent controversy, and the question of whether short-term clinical trials of medication can translate to the real-world, clinical environment is being answered with increasing skepticism.

Psychiatry's long tradition of clinical practice based on professional consensus rather than academic (or "hard") science has also served to retard the understanding of true clinical responses to psychotropic drugs. For example, it is common clinical practice to use serotonin reuptake inhibitors (SRIs) for the treatment of most forms of depression, in spite of evidence suggesting that tricyclic antidepressants (TCAs) may be more efficacious in treating severe depressions. In this instance, the negative effects of using consensus based, rather than science based, criteria are in all probability minimal. In other examples, however, consensus based psychiatric treatments have had significant negative repercussions on patient outcomes. The phenomenon of rapid neuroleptization, for instance, a common clinical practice in the past, is thought to have led to increased incidence of the potentially fatal neuroleptic malignant syndrome.

Although unappreciated by many psychologists, the gap between research and clinical psychopharmacology practice remains large. Some have attempted to rectify these disparities by constructing treatment algorithms that guide clinicians as to appropriate drug use. These efforts are still embryonic, and, unfortunately, treatment algorithms themselves may once again be developed on the basis of expert consensus rather than clinical science. Also, drug algorithms only address the pharmacologic aspects of treatment and rarely attempt to include psychosocial or other treatments (Rudorfer, 1995).

It is safe to assume that pharmacotherapy alone is not a sufficient condition for recovery from most forms of mental distress. Although it has been proposed that psychotherapy is an "occasionally indicated, delegatable" function (Klein, 1995, p. 81), examination of available evidence should temper any rush towards sole reliance on pharmacotherapy as an effective treatment strategy. For the most part, this is due to the reality that a substantial placebo effect operates in most psychotropic drug studies. The high rate of placebo responding to antidepressants is a particularly robust finding. Meta-analytic review of a large number of clinical trials of antidepressants indicated, for example, that while 60%–70% of depressed patients respond to drugs alone, approximately 35% displayed a therapeutic response to placebo. As a result, only around 25% of participants could be considered as true drug responders (Preskorn, 1996). Up to 70% of drug response in less severe depressions may be a placebo response. Indeed, the placebo response is so well demonstrated that some have suggested the clinical use of "pill placebo" as an effective intervention for depression (Brown, 1994). Sizable placebo responses have also been observed for other classes of psychoactive drugs as well, a fact which raises not only clinical concern but also methodological issues, as it is possible that many, if not most, patients in clinical trials can detect the differences between active drugs and placebos.

2.33.5.4 Aging Populations—Aging Programs

Although society continues to mature and age, as a profession, psychology continues not to prepare graduate students effectively for the challenges of caring for an older population (VandenBos & DeLeon, in press). Psychology training programs must be in the forefront of developing psychological based treatment programs targeted towards the needs of the elderly. Students in psychopharmacology will require far greater expertise than is currently available in most standard training programs if they are to provide adequately for the psychological and pharmacological needs of older Americans. The high rates of overprescription in elderly Americans has received wide comment. Programs educating physicians and other health care providers regarding rational use of psychopharmacologic agents have resulted in significant reductions in prescriptions written for elders. Given the importance of psychosocial factors in the care of the elderly, we would again rhetorically ask: are any of the professional schools demonstrating an interest in establishing psychology-based teaching programs in nursing homes?

2.33.6 HEALTH CARE COSTS

The growth in psychology reflects changes in health care in the USA. In 1950, the USA spent $13 billion or 4.4% of its gross national product (GNP), on health services. Twenty years later in 1970, the USA spent $75 billion or 7.5% of its GNP on health services. By 1980, this had increased to $250 billion or 9.4% of the GNP. In the 1990s, health spending increased to $740 billion or 13% of GNP, with estimates it would increase to more than 16% by the year 2000 and between 27% and 43% by the year 2030 (Bingaman, Frank, & Billy, 1993; Frank & Ross, 1995).

Increasing costs of this nature cannot be sustained by the US economy. Many believe that the increased cost of health care has been the driving force behind managed care. The federal government represents the largest health care payer in the USA. Federal health care programs (i.e., Medicare and Medicaid) have undergone substantial, uncontrolled growth. The federal government's share of health care spending rose from 28.1% in 1992 to 31.7% in 1993. In the six-year period between 1992 and 1998, Medicaid is projected to grow by 10.5%, and Medicare is expected to grow by 9.4%. This growth in spending stands in sharp contrast to other federal expenditure growth which is estimated, for the same period, to be 2.5% (Frank, Sullivan, & DeLeon, 1994).

2.33.6.1 The National Health Care Debate

Awareness of increasing costs of the health care system led to a national debate on overhauling the health care system in the early days of the Clinton Administration (Frank, 1993; Glueckauf, Frank, Bond, & McGrew, 1996). This debate resulted in no new immediate federal legislation. The functional outcome of the debate, however, was a transition to reform at the state level and reform through private markets. It has become clear that only incremental change is possible at the federal level (Frank & VandenBos, 1994).

Within private markets, fragmented care has often been viewed as a sizeable factor in the escalation of cost. Most patients have multiple providers, practicing in different settings, providing multiple work-ups and multiple prescriptions for treatment. This fragmentation of care leads to diminished accountability for outcomes. In addition, multiple providers create numerous opportunities for overdiagnosis, excessive treatment, and iatrogenic outcomes. Payers, aware of the cost of fragmentation, have focused on streamlining delivery systems that emphasize accountability by restricting access to patients.

Integrated service networks (ISNs) have been touted as an effective ingredient in the implementation of systems focusing on quality and accountability. In the 1993–1994 health care debates, several states considered proposals to legislate ISNs (Frank & Kivlahan, 1997). Although few states were successful in legislating this approach, the combined power of payers has functionally moved many delivery systems in this direction. ISNs are networks of organizations that provide, or arrange to provide, a coordinated continuity of services to a defined population for whom they are clinically and fiscally accountable for outcomes and the health status of the population served. Organized delivery systems may be created through the vertical integration of organizational services or through the virtual integration created through a series of contracts. The goals of organized delivery systems differ dramatically from the goals of single entities practicing in the fragmented health care system. While systems focus on singular patient encounters, ISNs or organized health care systems focus on the health of the community through prevention and health promotion. Integral to the development of these complex organizations is the use of "holographic organizations." In these organizations, constituent parts (i.e., key roles and services) are included in smaller delivery systems so that every aspect of the organization replicates the larger entity.

These evolving changes in organized delivery systems have critical implications for the practice of psychology. As organized delivery systems have become more dominant in the practice landscape, the solo practitioner has become an endangered species. Pressure to combine and to join specialty groups or multispecialty groups has been intense. Payers have used the "power of contracting" to exclude individuals who are not part of larger groups providing discounts and accountability.

It now appears that capitation will evolve differently in unique markets. While some markets will move towards massive levels of capitation as seen on the West Coast and some portions of the Midwest and Rocky Mountain areas, other areas such as the Southeast will be slower to become dominated by managed care. Indeed, there seem to be countervailing trends which suggest that even within high managed-care environments, the move towards capitation may be diminishing. Instead, there seems to be a trend towards point-of-service (POS) plans. In POS plans, participants are charged a slight surcharge in return for access to a wide range of providers. These plans have spread dramatically within California. Consumer demands for "choice" have increased options for broader provider panels. In many states legislation guaranteeing access to certain classes of providers, such as dermatology or OB/GYN, has become common.

There has been increased concern that capitated models place specialists at unreasonable risk. Primary care providers, by referring their most complex expensive cases to specialists, can remain under their cap and "dump" the most complex cases. In several highly penetrated managed-care markets, new trends emphasizing "episode of care" payment have become more apparent. In this model, care is "unbundled" so that the focus is on the individual case or the disease level. The Oxford Health Plan (Norwalk, CT) has committed its future growth to this model. Oxford is developing criteria for the start and completion of each episode of care. All care provided within a designated period is defined as part of this care episode. The practitioner receives a fixed, global price for services and all specialists bid on the provision of services within the disease episode. Importantly, in this model, there is emphasis upon cross-disciplinary teams.

Congruent with this approach is the growth of a number of specialized companies focusing on "disease management." For example, "for-profit" companies specializing in cancer, diabetes, asthma, and rehabilitation have now become common. Within ISNs, care of chronic disease conditions provided by several disciplines has become the method of delivery. Instead of vertical integration, these systems are horizontally integrated across the episode of care.

HealthSouth, a major rehabilitation company headquartered in Birmingham, AL, has often been touted as a classic example of this strategy. In 1982, HealthSouth was founded as an outpatient rehabilitation company. By 1997, it was fully operational in 30 large markets and HealthSouth facilities were located in all 50 states. Operating revenues grew from $25 million in 1991 to $2.4 billion in 1996, with a 28.2% operating margin in 1996.

Changes of this type have important implications for the practice of psychology. Increasingly, it has been recognized that psychology is a health specialty not merely a mental health specialty (DeLeon, Frank, & Wedding, 1995). Interestingly, a number of psychologists have taken another step and now consider themselves "primary care providers," rather than "specialists" of any type.

The slowness of this definitional recognition has come at high cost. During the 1993–1994 Congressional debate psychology mistakenly placed its primary emphasis upon mental health benefits. Arguing that each American was entitled to 52 sessions of psychotherapy per year, organized psychology emphasized an approach that had little likelihood of succeeding. Organized psychology pursued this strategy despite considerable evidence that this proposition would garner little external support. Late in the debate psychologists recognized that the narrow advocacy of mental health benefits, as opposed to suggesting changes in the broader health care arena, limited the ability of the profession to significantly impact the outcome of health reform conversations. This change in position led to recognition that psychology is a health profession. Interestingly, as many as 75% of all members of the APA identify themselves as "health care providers."

While psychologists initially contented themselves with narrow, self-defeating arguments, other groups staked out positions in the larger policy landscape. The American Medical Association, for example, led all other organizations in total contributions to political action committees during the national elections. In contrast, psychologists divided themselves into small, argumentative camps debating the veracity of each others' approach to the profession. The schism between academic psychology and the clinical practice community is marked, and in our judgment is extremely destructive.

2.33.6.2 The Town-gown Split

While American physicians have demonstrated loyalty to their training institutions, such leanings are rare in psychology. Many physicians have lamented the increasing pressure for clinical dollars within medical schools. This trend, however, demands medical school faculties engage in clinical practice and has assured that academic physicians are aware of trends within their profession and remain proficient clinicians. Psychology, in contrast, has followed a more "ivory tower science" approach. In many academic enterprises psychologists have little institutional incentive to be personally involved in clinical practice. Consequently, graduates of these programs who move into the practice community have little subsequent contact with their academic faculty. This creates schisms between the academic and clinical practitioners. Clinical practitioners come to believe that the academics understand little about their day-to-day lives. Such beliefs seem reasonable when few academic psychologists engage in actual clinical practice. Unfortunately, one result is that a true understanding of the drastic changes evolving in the health care delivery system is severely limited among those in many academic departments.

2.33.6.3 Self-identity

The failure of psychologists to identify with their academic training institutions has other implications. As the number of psychologists increase, they are moving into diverse settings. Increasingly, psychologists are moving into policy roles in addition to traditional clinical, academic, or science roles. There are numerous opportunities for psychologists in the public policy area. Behavioral science expertise is critical to health and educational programs. The demand for individuals with knowledge of these areas creates opportunities for psychologists. In addition, the broad purview of psychology training programs guarantees that graduates will continue to be sought for many diverse opportunities (Lorion, Iscoe, DeLeon, & VandenBos, 1996). Unfortunately, a tendency to be divorced from academic homes creates little common identification among psychologists. The tendency for different camps within psychology to devalue colleagues who work in different settings guarantees that a common identity is unlikely for the profession. As psychologists move into more diverse niches, this lack of common identity will continue to result in individual psychologists identifying more with their new opportunities, rather than with their profession in general.

It has been noted that physicians in policy settings identify strongly with their medical training. They assure that opportunities for physicians are developed through their policy positions and promulgated rules and regulations. In contrast, psychologists often seem to use a "scientific" approach to assessing the value of extending psychology into new settings. This approach requires empirical validation of the usefulness of psychologists for each and every niche. The tendency for psychologists within different camps to devalue each other exacerbates this problem.

2.33.6.4 The Congressional Science Fellowship Program

Several programs have created special opportunities for psychologists to learn more about health policy formulation on a "first hand" basis. Although psychology curriculae rarely emphasize either health policy or public health, the broad training psychologists receive is ideal for the evaluation of policy issues.

In 1974, the APA created the Congressional Science Fellowship program. This program has now been responsible for facilitating the involvement of 61 individual psychologists in policy-making and the political process. Through the APA Fellowship, psychology's expertise is systematically applied to society's priorities. The program allows psychologists to spend a year in Washington, DC working in the legislative or administrative branches. Through this "hands on" experience, psychologists have the opportunity to see (and participate in) national public policy being made on a first-hand basis. Upon completing their Capitol Hill experience, approximately half of the Fellows take policy-related positions within various agencies, while the other half return to their previous positions.

Another program that holds tremendous opportunity, but which unfortunately has been only rarely considered by psychologists, is the Robert Wood Johnson Health Policy Fellowship (RWJ). Like the APA Fellowship, this program was created in the mid-1970s to provide mid-career academic health center faculty the opportunity to learn about public policy through actual experiences. The RWJ Fellowship is administered by the Institute of Medicine (IOM) at the National Academies of Sciences. Each year, through a competitive process, a few are selected from academic health centers and invited to spend a year in Washington, DC working within the legislative or administrative branches. Again, most RWJ Fellows choose to work within the Legislative Branch. The program provides an extensive didactic training on health policy prior to the actual Fellowship experience. Fellows are exposed to leaders from virtually every sector of the American health care system. After the didactic sessions are completed, fellows spend 10–14 months working on federal health policy. To date, only two psychologists have taken advantage of the RWJ—Danny Wedding and Robert G. Frank.

Within health care, there are many critical issues which will affect the future of professional psychology. In the late 1990s most psychologists are concerned with those changes in health care delivery that impact their own economic status. Without question, such concerns are vital to the future of individual psychologists in practice. On the larger scale, however, psychology as a profession must be concerned about issues which open up new markets and expand the scope of practice, such as the acquisition of the ability to prescribe medication (DeLeon & Wiggins, 1996). In the 1980s concerns were voiced within the profession regarding whether it should seek authority to admit to hospitals. Each of these professional expansion decisions is critical to the future and vitality of the profession and each reflects the interface between psychology and organized medicine. For each issue, organized medicine has a history of standing between psychology and the ability to achieve the goal. As concerns regarding the number of providers and the level of utilization of health care services have increased, all types of health professionals have found themselves pitted against each other in a battle to win the health care dollar.

Since the 1890s organized medicine has demonstrated that it is the most effective health profession in the public relations arena. Starting at the turn of the twentieth century, organized medicine teamed with hospitals to create the ultimate public relations campaign. These organizations created the concept that health care must be provided by physicians in hospitals to assure the health and well-being of the American people. While there are clearly elements of truth within this premise, the most striking aspect of this partnership was the ability of these two groups to essentially vanquish other competitors such as osteopathic medicine.

2.33.6.5 The Professional School Movement

Organized medicine has been nothing short of remarkably successful at convincing the American public they should, using tax dollars, finance the education of American physicians. Starting with the passage of Medicare in 1965, taxpayers have subsidized the training of each American physician. These subsidies support both medical school education and, to a larger degree, training in residencies. Despite the fact that it now appears there is a clear excess of specialist physicians in the US, since the 1960s Americans have provided extraordinary subsidization for the training of American physicians. In 1997 alone, each American spent $48.91 on graduate medical education (GME). Annually, the federal government spends about $75 000 for each resident in training. The overall cost of the GME program exceeded $6 billion in 1997 (Medicare Payment Advisory Commission [MedPAC], 1997). Provisions included in the Balanced Budget Act of 1997 are expected to begin to curtail the program.

There is an important "reverse psychology" to the marketing support for graduate medical education. Simply put, if Americans spend this much to support the training of their physicians, physicians must be more valuable than any other health professionals. Indeed, if one examines the record of support for other health professions it is negligible in contrast to the monies provided to physician training.

Psychology, in particular, receives a very limited amount of support under Title VII (the Health Professions provisions) of the Public Health Service Act. Although medicine and the other nonphysician health care professions receive support under this initiative, support for psychology's internships or residencies is virtually nonexistent. It is the inclusion of physicians and professional nursing under GME and Title VII (or VIII for nursing) that creates the circular outcome that more money must be spent on physician training and advanced practice nursing and less on other health professions. Since psychologists are not formally included under the various federal government training programs, the limited value of the profession to the health of the nation is continuously demonstrated. Without inclusion, it is unlikely that psychology will become a critical health profession in the USA (Dunivin, 1994). And, since the vast majority of psychology's graduate students are now within professional schools, it is their leadership that must steer this legislative recognition.

2.33.7 OPPORTUNITIES FOR THE FUTURE

As psychologists have transitioned from mental health providers to health care providers, the opportunities have never been greater (Johnstone et al., 1995). Since the 1970s the field of psychology has changed substantially. One simple indication of the magnitude of this change is the increase in the number of psychologists. Between 1974 and 1990, it is estimated that the number of psychologists increased by 300%. This growth was accompanied by a 72% increase in the number of psychology training programs. If these estimates are correct, psychology's overall workforce increased from a ratio of 8.6 psychologists per 100 000 people in 1959 to nearly 22.4 psychologists per 100 000 people in 1989. There are definitely the numbers to be a major player in the legislative and health care arenas.

To cite one concrete example of an evolving opportunity: in the late 1990s, as many as 100 million Americans have chronic health conditions that limit one or more of their activities. Chronic health conditions engender significant cost. Individuals with activity limitations account for only 17% of the population but 40% of all medical expenditures. The per capita cost for individuals with chronic conditions are three times greater than individuals without these conditions.

Psychologists frequently care for individuals with chronic health conditions. Within settings such as rehabilitation hospitals, psychologists perform diverse activities ranging from provision of direct psychological care to the organization and management of all services to individuals with disabilities. In each of these examples psychologists are critical to the well-being of these individuals with chronic health conditions. The overall value of psychologist contributors in these types of health settings is intuitive but not well demonstrated empirically. Undoubtedly, as is reflected by the trend towards disease management models, more attention will be directed toward chronic health conditions in the future. Psychologists have the opportunity to demonstrate their critical role in treating those who are afflicted with chronic conditions.

It is a political and public policy decision as to which profession's training programs will be supported by the federal government. Psychology possesses the numbers, maturation, and clinical value to qualify. The underlying issue is: do psychologists collectively possess the necessary political will? There are many areas within the health care system in which psychological expertise can make a very real difference in the lives of the nation's citizens. The underlying question remains, however: will the next generation of psychologists take up the challenge?

2.33.8 CONCLUSION

Psychology is one of the "learned professions" and as such, possesses the responsibility of effectively addressing society's pressing needs. During the past decade, our nation's health care system has undergone tremendous structural changes which have had direct implications for the profession. These have not been easy times for the profession, especially for those in solo private practice. There has been an unprecedented acceptance of managed care, increasing requirements for professional accountability and the provision of cost-effective services, and a gradual awareness of the clinical potential inherent in technological advances within the communications and computer industries—that is, telehealth. Simultaneously, with the advent of the professional school movement there has been an exponential growth in the number of professional psychologists.

The period to 2010 will provide professional psychology with numerous opportunities and challenges. To survive and flourish, the profession must internally decide what are its strengths and where can it best excel—psychology is no longer merely one of the mental health professions. Psychologists must ensure that their academic and practice communities work together to address society's needs. Concerted efforts, especially by the leadership of the professional schools, must be made to ensure that psychology is expressly recognized as one of the health professions throughout the federal government's reimbursement and health training initiatives (i.e., GME and Title VII). The profession must further systematically seek to ensure that its "scope of practice" reflects advances in training, including obtaining prescription privileges and working collaboratively throughout the health care arena.

The behavioral sciences and specifically psychology have much to offer to the nation's health care struggles. It is unclear, however, whether the next generation of graduates is collectively willing to become personally involved in the necessary political and public policy endeavors.

2.34.1 CHANGE AND INSTABILITY: CONTEXT FOR MANAGED BEHAVIORAL HEALTH CARE

The delivery of behavioral health care services can be characterized by a process of continuous, if not at times chaotic, changes in response to a rapidly evolving health care environment and instability in the role of the behavioral health care provider in providing services to consumers. It is easy, if not simplistic, to view the changes as precipitated by the advent of managed care itself, but the evolution of managed behavioral health care lies in the behavioral health service system itself and the economics of providing behavioral health care services (Feldman, 1993; Mechanic, Schlesinger, & McAlpine, 1995). The context for the development of managed behavioral health care was, at least in part, provided by the system for delivering behavioral health services. In particular, four aspects of the delivery system provided context for the development of managed behavioral health care.

(i) Diversity in the professional categories of providers delivering behavioral health care services and the training associated with each category of provider to provide behavioral health care services

(ii) Variety in the therapeutic orientation(s) of the behavioral health care providers even within any given professional category of provider.

(iii) Variance in the modalities of treatment available for individuals with mental disorders with limited information to compare the outcome of care by modality.

(iv) Fragmentation in the continuity of care for individuals across levels of care or between providers within the same level of care.

While these characteristics of the delivery system could have been valuable in generating multiple approaches to the challenges of providing services to individuals with mental disorders, instead these characteristics led to confusion for the consumer and added costs for the payor. There was little in the way of consensus-based decision-making for matching a consumer's behavioral health care needs with a type of provider (or providers) best able to deliver the recommended modality (or modalities) of treatment to achieve the optimal outcome for the individual for the dollar spent on service. Each individual was on his or her own to navigate the delivery system and each payer complained that there must be a better way to attain value for the health care dollar. Managed behavioral health care grew out of an effort to stem the raising costs of mental health and substance abuse services, while rationalizing a delivery system that appeared fragmented and confusing to consumers and payors (Berlant, Trabin, & Anderson, 1994).

2.34.2 CONCEPTS OF MANAGED BEHAVIORAL HEALTH CARE

Managed behavioral health care, as an industry, is frequently characterized as a single program without differentiation. However, the reality is that managed behavioral health care organizations vary by key dimensions in a matrix of the: type of program(s) offered, populations served, service delivery system(s) offered, benefit(s) managed, and funding arrangement(s) offered to purchasers. Each of these characteristics in combination can create a significantly different type of managed behavioral health care program with differing impacts on the consumers and providers of services.

2.34.2.1 Types of Programs

It is difficult to discuss the management of care separately from the delivery system that is providing the care. However, it is an important feature of managed behavioral health care to track where the roles of the manager and provider of care are the same and where these roles diverge. It is equally important to note the ability of the managed behavioral health care organization to direct consumers within the delivery system. The types of behavioral health care management can be seen in three broad categories of patient care management: (i) utilization management, (ii) staff practice management, or (iii) network management.

Utilization management is one of the earlier forms of managed behavioral health care derived from the peer review process. At its core, this form of managed behavioral health care consists of a review of the care, either inpatient or outpatient, conducted prospectively, concurrently, or retrospectively, to determine if the care being recommended or the care being provided meets the criteria of being medically necessary. A variant of utilization management is applying the utilization management principles for individuals with catastrophic or high-risk conditions only leading to intensive utilization management for a circumscribed group of individuals with high-risk conditions. For the consumer, utilization management does little to assist the individual in navigating among the categories of professional providers offering services, evaluating the appropriate treatment options, or monitoring the quality of care received. For the purchaser, utilization management contains the cost of care, but does little to assure that the health care dollar is being spent wisely. For the provider, utilization review entails constantly building a case for the medical necessity of the care being recommended and risking that a reviewer will not make the same determination as the provider putting payment for services at risk. One of the most appealing aspects of a utilization review program, from the consumer and provider perspectives, is that this form of managed care is essentially nondirectional in that the managed behavioral health care organization is not directing the consumer to any particular provider. Instead, the managed behavioral health care organization is making a medical necessity determination regarding the care that is being provided or recommended without directing the consumer to a particular provider. The provider continues to be the provider and manager of care with a peer reviewer overseeing the medical necessity of care for reimbursement purposes.

A staff model delivery of care has long been a mainstay of the publicly funded health care delivery system, but has become more common with staff model health maintenance organizations that delivered managed behavioral health care through a staff model environment (Feldman, 1994). At the core of staff model delivery systems is the delivery and management of most, if not all, of the behavioral health care services needed by a population of members through staff providers. All services required by members are provided through the staff model delivery system and any services needed outside of the staff model delivery system must be preauthorized by a representative of the staff model delivery system. Management of the care continues to rest with the staff model provider.

While this model worked well in areas with high geographic concentrations of members and where mental health care was integrated with other health care, it tended to not work as well for accounts with a wide geographic dispersion of members and where the health care was not well integrated with other health care options. National employers with multiple health care plans tended to not opt for staff models except in selected geographic areas with a high concentration of employees. For consumers their options were limited to receiving care through the staff model delivery system, with the attendant pressure on evening and weekend appointments. For providers there was no access to these consumers unless the provider was a member of the staff delivery system. For purchasers the options were clearer, tighter quality control was possible and costs contained, but the choice and access to providers was limited to the staff model delivery system.

Most staff model delivery systems have evolved into mixed staff and network model delivery systems, partly to respond to consumer need for greater choice and access to providers, but also to respond to the economic need to have providers in geographically distributed areas and to have a range of behavioral health care subspecialists, yet not having enough membership in areas to support a full staff model. Network providers augmented the existing staff model delivery system, providing greater geographic coverage, better access to appointments for consumers, and a wider array of subspecialty expertise. The development of mixed staff and network model delivery systems helped expand the range of health plans within geographic regions, but continued to have difficulty in meeting the needs of the national or regional employers who wanted consistency in the delivery of behavioral health care benefits. With the management of care within mixed staff and network model delivery systems, it became increasingly difficult to ensure that the treatment protocols and guidelines followed by the staff model delivery system were being applied equally and effectively across the panel of network providers. The larger the panel of network providers, the less likelihood of the provider feeling closely affiliated to the culture, the practice, and the economics of the health plan. The provider within the staff model delivery system maintained dual roles as the provider and internal manager of the care and an external manager of care provided within the network.

In response to national and regional employers, managed behavioral health organizations created national networks of participating providers all credentialed to meet standard requirements and included in practice management efforts to ensure some minimal consistency in the management of care. To guide the consumer to the manager of care was a representative of the managed behavioral health care organization, typically a behavioral health clinician, whose task was to assess the immediate needs of the consumer and match the consumer to the provider(s) within the network best able to initiate treatment. In the network model delivery system, the role of the provider and manager of care became truly separate. The manager of care became the consumer advocate coordinating aspects of care delivered through a provider delivery system and became responsible for overseeing the quality and outcome of care delivered by the provider. Purchasers of behavioral health care benefits could solve the dilemma of the diversity of providers, treatment modalities, outcome management methodologies and cost by holding a single managed behavioral health care organization accountable for all the complexity in the field, while retaining control of the quality of services and cost of care. For the consumer, the network model delivered wider access to providers with greater standardization in practice and a consumer advocate to coordinate care. For the provider, the network management model took away a key functional role in the management of care and left the provider struggling with the boundary between providing and managing care.

2.34.2.2 Populations Served

The population of patients to be served by managed behavioral health care organizations can also vary along key dimensions, such as the need for service and utilization of resources, demographic characteristics of the patient population, presence of comorbid medical/health conditions, and previous mental health and/or substance abuse treatment. An understanding of the population to be served provides the basis for the pricing and underwriting assumptions associated with the funding for the cost of care and for the design of the types of programs that will be offered.

2.34.2.2.1 Need for service and utilization of resources

A population-based perspective requires the examination of individuals in five broad clusters:

(i) those who *do not need* mental health and/or substance abuse services and *do not seek* those services;

(ii) those who *do need* mental health and/or substance abuse services and *do not seek* those services;

(iii) those who *do need* mental health and/or substance abuse service and *seek inappropriate* services;

(iv) those who *do need* mental health and/or substance abuse services and *do seek* those appropriately; and

(v) those who *do not need* mental health and/or substance abuse services, *yet seek* the services anyway.

Each cluster has a different impact on the managed behavioral health care organization, the broader health plan, the providers within the managed behavioral health care organization and the health plan organization, the consumer and his/her family, and the society in which the individual resides and the resources needed to sustain public health.

2.34.2.2.2 Demographic variables

Within these broad clusters, there are also the more traditional demographic characteristics of populations, including age, gender, marital status, and geographic location of residence. The demographic characteristics are typically available as part of a membership eligibility database determined at the time that the individual and his or her eligible dependents were enrolled within a health care program. These same membership eligibility databases tend to exclude information that would provide additional insight into the impacted populations, such as racial/ethnic affiliation, educational, occupational, and income level. These are variables that are sometimes inferred, but the absence of data on the broad population limits some of the programming that can be developed to address specific needs.

2.34.2.2.3 Presence of comorbid medical/health conditions

An intersecting population-based variable is the presence or absence of a comorbid medical/health condition. This variable is bidirectional. Individuals with one or more significant comorbid medical/health condition(s) may not have a specific mental health diagnosis, yet may experience an improved outcome with the presence of focused behavioral health intervention (Barlow, 1994a, 1994b). A good example is the improved mortality rate for individuals with breast cancer who receive a focused behavioral health intervention in conjunction with the prescribed treatment regimen as compared to those individuals receiving the treatment regimen without the behavioral health intervention. For individuals with an identifiable mental health diagnosis, the provision of behavioral health services may be complicated by the presence of one or more comorbid medical/health condition(s) (Pallak, Cummings, Dorken, & Henke, 1994). An example would be the difficulty in providing treatment for a reoccurring major depressive disorder with an individual who had recently undergone an organ transplant procedure. While the examples may seem obvious, the population-based variables related to the incidence and prevalence of medical/health conditions within a given population will influence the type of managed behavioral health care program and the funding to make the services available to individuals.

2.34.2.2.4 Presence of previous mental health and/or substance abuse treatment

If past behavior is the best predictor of future behavior, then previous mental health and/or substance abuse treatment is one of the indicators of the presence of serious and/or persistent mental illness. Approximately only one of five people suffering from a mental disorder seeks treatment, suggesting a significant unmet need in services. These individuals are likely to use the general medical delivery system, thereby increasing the overall health care costs (Pallak, et al., 1994).

2.34.2.3 Service Delivery Systems

Behavioral health care services have historically been offered in one of two types of delivery systems, either open access to any licensed provider or through staff model community based treatment programs. Managed behavioral health care organizations brought an array of other options for service delivery systems, including directed access, guided access, delegated access and integrated delivery systems.

2.34.2.3.1 Open access

Open access to any licensed provider had been the delivery system associated with indemnity insurance programs with the only limitation on service being an annual and/or lifetime benefit maximum. For consumers not covered under an indemnity insurance program, community mental health centers and other publicly funded community treatment resources were available for consumers seeking mental health and substance abuse specialty care. Additionally, mental health and substance abuse services were offered through staff model treatment programs associated with many staff model based health plans. The first limitation placed on an open-access delivery system was the establishment of a contracted panel or network of providers. However, most health insurance plans continued to market their traditional indemnity program as having in excess of 95% or more of all available physicians in a geographic area as an incentive for consumers to select their insurance product leading to an essentially open access to almost any licensed provider. These contracted networks, however, were built for a health insurance product, and, for the most part, determined that any licensed provider meant any licensed physician. Many of the contracted networks for indemnity insurance products excluded psychologists and rarely included any other mental health professional types. When psychologists were included, it was not with the intent to include broad participation, but tended to include psychologists in practice with a contracted network physician or psychologists with specific expertise that was not covered by the contracted network physician panel. Consumer access to nonphysician behavioral health care providers was limited to referral by a physician within the contracted network physician panel. Physicians made relatively few referrals, particularly for outpatient-based services, and referrals for inpatient-based services were made when a patient was in acute need of that level of care, which typically meant in need of a psychiatrist. As psychologists, other mental health professionals and consumers applied pressure to health insurance plans to include them as part of the contracted network of providers, health insurance plans turned to managed behavioral health care organizations to manage the diversity of behavioral health care providers and the challenges of credentialing and contracting with a network of specialists in the treatment of mental health and substance abuse disorders.

2.34.2.3.2 Directed access

Managed behavioral health care organizations brought a new twist to the development of contracted networks, the ability to contract with a wide array of behavioral health care providers by having credentialing standards specific to each professional category. Managed behavioral health care organizations also brought the subspecialty expertise needed to differentiate between the types of services offered by the behavioral health care provider and the levels of care available in the treatment continuum. Managed behavioral health care organizations created the network to handle all mental health and substance abuse service needs and created the basis for "carving out" the mental health and substance services from the health plan product. The consumer was offered the opportunity to access services through the managed behavioral health care organization directly rather than exclusively through the contracted network of physicians for the health plan. This development led to what has become known as a "gate-kept" model for service delivery. Because the consumer no longer needed to access services through a network physician for the health plan, access to the specialty mental health care network was directed by a representative, typically a clinician, of the managed behavioral health care organization to the provider (or providers) in the network able to address the consumers needs.

Directed access continues to exist, primarily in programs associated with health maintenance organizations, and where the services are provided within a more defined geographic area. The intent is to have a defined group of quality, multidisciplinary behavioral health care providers who can function as a part of an organized health care system and to discourage consumers from seeking services outside of the organized health care system both for cost and quality of care concerns. The development of directed access delivery systems also led to a significant decrease in the number of providers needed to deliver mental health and substance abuse services.

2.34.2.3.3 *Guided access*

Managed behavioral health care organizations also needed to address the requirements of purchasers, typically large employer groups, who desired access to a specialty mental health and substance abuse contracted network and wanted to permit consumers the ability to have broad access to providers. Consumer requirements drove the modifications to the directed access model of service delivery. In particular, consumers were concerned about the continuity of care and played an active role in nominating providers to be included in the network to minimize the disruption in care when a managed behavioral health care program was implemented. Consumers also found value in having a clinician at the managed behavioral health care organizations who was able to discuss the consumer's unique needs and able to assist the consumer by providing information about types of providers, types of treatment modalities, and expectations of treatment. The clinician at the managed behavioral health care organization became the consumer's advocate in jointly determining what services were needed, ensuring that the consumer had the referral(s) needed to address the situation, and creating options for flexible case management.

The guided access delivery system is inherently a more expensive program. However, from the consumer's perspective, it reduced the discontinuity of care created by more directed access programs and reduced the fragmentation that plagued the historic delivery system because the care was now more flexibly coordinated. Providers bemoaning the intrusion of managed behavioral health organizations into the treatment planning process would be surprised at the number of questions that consumers have regarding the provision of mental health and substance abuse services that consumers are unwilling or unable to address with a provider directly.

2.34.2.3.4 *Delegated access*

Perhaps one of the older forms of delegated access has been the community mental health center program. In delegated access delivery systems, a delivery system is designated as the entry point into the array of options offered by the delivery system. With community mental health centers, the designation as the point of entry was based on geographic catchment areas. To enhance access, many community mental health centers also created satellite sites to improve the availability of entry points. As the consumer entered the delivery system, the providers within the system were delegated the responsibility for managing the care within the limits of what was available using other systems, such as the state hospital system, when needed. Just as guided access to the delivery system was driven by consumer needs, delegated access to the delivery system was driven by provider needs, particularly organized group practices.

Many organized group practices have developed expertise in some of the key elements of the management of behavioral health care services and have positioned themselves as being capable of delivering those services with minimal oversight. Purchasers of managed behavioral health care services have also recognized the role that the organized group practices can play in minimizing administrative costs associated with managed behavioral, yet have remained concerned about handing the entirety of the process over to organized group practices who do not have the significant infrastructure found within managed behavioral health care organizations.

Managed behavioral health organizations have, for the most part, developed various programs for assessing the capacities of organized group practices to manage care, delegating key elements of the clinical management process, and overseeing the quality of care within the group practice. The implementation of a delegated access model can occur with or without any difference in the payment or funding methodology. In other words, organized group practices may have delegated access to outpatient services in which the group is paid on a fee-for-servicebasis, a discounted fee-for-service basis, a case rate basis, or a subcapitated basis. The payment methodology does not dictate the delegated arrangement, but may become a component of the arrangement. This is an important point to make in a time when many providers are seeking to take financial risk for care costs to gain control over the management of care. These are indeed separate issues and providers need to carefully evaluate their capacity to assume risk with the possibility of adverse selection across a smaller population base.

2.34.2.3.5 *Integrated delivery systems*

Integrated delivery system is a complex concept that means many different things depending upon one's perspective within the delivery system. One notion of an integrated delivery system was the concept of placing all the required levels of care within one integrated delivery system which will allow the purchaser and consumer of health care service to receive all the needed services within a seamless delivery system that would facilitate the needed access to the appropriate level of care at the appropriate time. The difficulty for integrated delivery systems within the behavioral health care arena is that relatively few individuals need the full range of integrated delivery system services. Integrated delivery systems do offer advantages under a case rate payment methodology for those individuals who will need the full continuum of services to manage an episode of care (i.e., inpatient hospitalization, partial hospitalization, intensive outpatient treatment, and ongoing outpatient treatment for maintenance and stabilization), but it is more difficult to have all individuals receive services from a single integrated delivery system because of the consumer issues raised under the directed access model.

Another notion of an integrated delivery system is the concept of providing managed behavioral health care services within a broader health care system. In some ways we have come full circle back to the original notion of delivering direct staff model services within a broader health plan delivery system such as a health maintenance program. Most managed behavioral health care organizations have created mechanisms to imbed the behavioral health services within a broader health plan delivery system by offering direct delivery of services (through staff or contracted clinicians) or by creating a subnetwork of specialty providers that function as the behavioral health service division within the broader health plan meeting the requirements of the health plan for integrated care.

The current state of the managed behavioral health care industry is that most managed behavioral health care organizations have some form of all of the options for delivery system access present within their networks. The terminology may vary from organization to organization, but the concept is a tiered network strategy built upon concentric circles. The widest element of the circle is the universe of all providers which is growing at an exponential rate, followed by the universe of contracted network providers, followed by yet smaller subsets of providers who have one or more specialty arrangements with a managed behavioral health care organization to address specific purchaser or consumer needs.

A provider's experience with a managed behavioral health care organization will be strongly shaped by the nature of the delivery system(s) within which he or she is providing services.

2.34.2.4 Benefits Managed

It goes without saying that health care benefits vary widely. But particularly in the area of mental health and/or substance abuse benefits, the variability is enormous. The variability in access to benefits has led to the extension of the Medicaid program to cover the uninsured and to the parity initiatives on the state and federal level.

Managed behavioral health care organizations can only manage an existing benefit. They can work to improve access and accountability for a limited benefit, but cannot change an existing benefit into a better benefit or create a benefit where one does not exist. Many consumers do not separately consider their mental health and/or substance abuse needs when selecting a health plan. Cost is still typically the primary consideration. Instead, the consumer typically becomes aware of a mental health and/or substance abuse benefit when a crisis emerges.

2.34.2.5 Funding Arrangements Offered

The funding arrangements for managed behavioral health care organizations have two components, the cost of care and the cost of the management of the care. There are three basic types of funding arrangements for managed behavioral health care organizations: (i) administrative services only (ASO), (ii) capitation, and (iii) performance-based risk corridor(s). Everything else is variation on a theme.

ASO is a funding arrangement in which the managed behavioral health care organization is paid for the services rendered in the management of the care. It does not include the cost of the care itself, although the services provided by the managed behavioral health care organization can be quite extensive. The services can include the costs associated with building and maintaining a broad national network, paying claims, handling all reporting requirements, providing 24 hour access to members, and coordinating all aspects of patient care.

Capitation is a funding arrangement in which the managed behavioral health care organization is provided the funds for the cost of care and for the services rendered in the management of care. The cost of care is determined by historical utilization of care when that data is available or by comparing the member characteristics and benefit structure with other comparable accounts and estimating utilization. The cost of care equation has two components, the utilization of services and the unit cost per service. Capitation has particularly impacted psychologists in clinical practice because of the cost per unit of service. The master's-prepared therapists have been willing to contract for a lower cost per unit of service. Physicians have been required inpatient and medication management services, which has enabled them to retain greater leverage on the cost per unit of service. Psychologists have been caught between the two.

Performance-based risk corridor funding has been a mechanism used by purchasers for ensuring accountability in managing the behavioral health care benefit. The managed behavioral health care organization places some or all of their administrative fee at risk for performance within a prescribed corridor along any number of dimensions. Corridors can be established around any number of performance indicators, such as utilization, member satisfaction, timeliness of reporting, and accuracy of claims processing. Corridors can also be established around the cost of care, allowing the managed behavioral health care organization to participate in the cost savings associated with containing the cost of care or to share in the risk associated with failing to meet the cost of care expectations.

Managed behavioral health care organizations are judged by the membership and the revenue associated with the membership. The revenue associated with ASO funding and performance-based risk corridor funding is much more limited than the funding associated with capitation because the cost of care is not included in the revenue equation. The risk associated with adverse selection is also embedded in the revenue associated with capitation, particularly in membership populations in which the historical utilization is not completely known or where the benefit has changed.

A survey conducted in 1995 suggested that of 185.7 million Americans with health insurance, over half (58.2% or 108 million) were enrolled in a managed behavioral health care organization. Managed behavioral health care revenues for 1994 were approximately $2.1 billion with approximately 20% of the membership enrolled in risk-based (capitation), network-based programs and 20% enrolled in nonrisk-based networks and the remainder in hybrid programs, including significant numbers of members involved in employee assistance programs (Oss, 1995).

2.34.3 QUALITY AND ACCOUNTABILITY

The value-added promise of managed behavioral health care organizations has been to improve the quality and accountability within the behavioral health care field by providing objective indicators of quality of care (Marques, Geraty, Harbin, Hoover, & Theis, 1994). The challenge lies more in the promise than in the reality. Managed behavioral health care organizations are poised to have all of the elements necessary to make a significant contribution to the quality of behavioral health care service. Poised because managed behavioral health care organizations have:

(i) access to health care data,
(ii) management information systems to support the collection of health-care data,
(iii) opportunities for outcomes measurement, and
(iv) infrastructures to support evaluation and analysis.

To date, the reality, for the most part, has been short of the opportunity.

2.34.3.1 Access to Health Care Data

All of the managed behavioral health care organizations are gathering enormous quantities of data. Expectations for the ways in which the data could be used have risen dramatically over the past five years. The major questions that impact managed behavioral health care organizations revolve around the internal issues related to the availability of the data, the currency of the data, the integrity of the data, the applicability of the data to questions pertaining to the outcome of care. Questions also revolve around the externally focused issues related to the ability to share the data within the concerns for privacy of health care data, the competitive nature of the organizations and the regulatory pressures impacting the industry. The good news is the increasing efforts at standardization of sets of data used by health care systems and managed behavioral health care organizations. The American Managed Behavioral Healthcare Association (AMBHA) established its own performance indicators for managed behavioral health care organizations in its Performance Measures for Managed Behavioral Health Care Programs (PERMS 1.0) initiative which prompted the members of AMBHA to begin capturing data and reporting comparative data in a common format structure (AMBHA, 1995). The bad news is the increasing expectations by purchasers and consumers about the timeliness, user-friendliness, and accessibility of the data. The corresponding expectations and costs to the managed behavioral health care organizations are shared with the providers, increasing the administrative workload on the providers to supply and audit needed data. There has also been another subtle, but significant, shift in the expectations regarding data availability. The shift is away from a retrospective framework to a more continuous, dynamic framework for the applicability of data. An example might help illustrate the shift. Managed behavioral health care organizations have been collecting patient or member satisfaction data for a number of years, yet that data reflects a retrospective evaluation of member satisfaction with a provider during a specified period of time that predates the survey process. The current purchaser and consumer environment places a premium on receiving that member feedback immediately following the receipt of service, incorporating the data into a dynamic provider profiling tool which then guides the next referral to that provider. The expectation in most cases exceeds the reality, however, the trend is definitely for data availability on a continuous or "real time" manner coupled with the expectation that the data will be used to manage providers and direct care (Bengen-Seltzer, 1995).

2.34.3.2 Management Information Systems to Support the Collection of Health Care Data

The search for the management information system optimized to meet the needs of managed care has been akin to the search for the Holy Grail. Most managed behavioral health care organizations are utilizing management information systems that were originally designed for managed health care, in particular, for utilization review programs. These management information systems do not provide the flexibility needed, in general, to address the current and changing needs of the managed behavioral health care environment.

Managed behavioral health care organizations that have grown through acquisition tend to have "legacy" systems that become a part of the system platform. Managed behavioral health care organizations that have grown through adding new membership in the rapid growth environment of the field have not been able to keep their management information systems updated due to the focus on rapid growth and expansion. Managed behavioral health care organizations that have not grown do not tend to have the resources to allocate to management information system infrastructure development.

On the positive side of the equation, managed behavioral health care organizations have placed a premium on flexibility in the design of the management information systems which has led to systems that are less rigid in architecture, more amenable to customization and change, more modular in their ability to connect to other applications, and better able to integrate with multiple claims payment systems. The fact that these management information systems are built from a flexible platform affords a better opportunity to electronically interface with providers than the structured systems used by health insurance plans.

2.34.3.3 Opportunities for Outcomes Measurement

A similar shift is occurring in the outcomes measurement activities. More traditional indicators of outcome had been evaluated against criteria of reliability and validity. Currently, indicators of outcome have the additional pressure of being confronted by business realities. Managed behavioral health care organizations are using outcomes measurement as one key aspect in the management of the network or providers. The demand is stemming from employers and purchasers of health care services to provide meaningful measures of patient improvement and treatment effectiveness and that the data is collected on an ongoing basis and used in decision-making regarding referral and continued care (Bengen-Seltzer, 1995).

2.34.3.4 Infrastructure to Support Evaluation and Analysis

This is the most vulnerable area within managed care organizations and has led to the development of strategic partnerships with academic and research institutions to provide the independence of evaluation and analysis. In the infancy of managed behavioral health care, much of the data was held as proprietary to the organization and not available for independent review. Given the highly competitive nature of the industry, the position was understandable. However, managed care organizations also had difficulty gaining acceptance of their research and evaluation efforts because of the taint of the information being collected for marketing purposes and had not being subjected to peer review processes. Currently the environment is opening up for collaborative approaches to addressing mental health and substance abuse policy issues with federally funded initiatives and through collaboration with research and training institutions.

2.34.4 IMPACT OF THE ADVOCACY AND CONSUMER MOVEMENTS

In evaluating managed behavioral health care organizations, one cannot underestimate the impact of the advocacy and consumer movements. Both forces have place mental health care at the forefront of a powerful political agenda to bring parity to the federal and state legislative bodies and worked to remove the stigma of mental illness. The parity movement itself would have had a more difficult uphill struggle without the real world experience of the managed behavioral health care organizations in managing care within even unlimited benefit environments. Parity, in the absence of methodologies for managing care, would have been a very difficult initiative to convince purchasers of health care services that the costs would not accelerate exponentially. The data from managed behavioral health care organizations currently providing services in states with parity initiatives implemented provided a basis for the cost estimates associated with the federal parity initiative. Increasingly, the coalitions to shape the mental health and substance abuse policies have forged partnerships between the managers of care and the individuals and advocates most interested in the behavioral services available for those most in need of those services.

2.34.5 PROMISE AND CHALLENGE OF PSYCHOLOGY

Training and education. There have been numerous discussions regarding the number of mental health providers who are entering the field each year and whether there is a surplus of providers. There is a perspective that has been shaped by years of working within managed behavioral health care organizations that can be shared. By all indicators, there is indeed a surplus of mental health providers. The more significant variable, though, is where are the providers electing to deliver service. In any major standard metropolitan area, there is a high likelihood that any given managed behavioral health care organization has a surplus of providers and has closed the network to new providers in that area or has restricted access into the network to providers with particular expertise (most frequently child and adolescent psychiatrists). However, the semirural and rural areas of the country continue to be seriously underserved by behavioral health care providers, as are the urban, inner-city areas, where some of the need for behavioral health care services is the greatest. If psychologists are to make a case for the early identification and timely treatment to address the unmet need and to support more equitable access to coverage for mental health and substance abuse disorders as afforded under various state and federal parity initiatives, the profession will need to actively address the distribution of resources to deliver the required services in underserved areas.

The second part of the discussion is focused on whether the training that psychologists receive has prepared them for the environment into which they will enter. Psychologists frequently report feeling professionally "squeezed" in managed behavioral health care networks between psychiatrists, who because of their medical training and licensure are uniquely situated to provide medication management and inpatient hospital based services, and other master's-prepared therapists, who may be more likely to accept a lower rate of reimbursement than psychologists. The concern seems to stem from the perceived lack of differentiation for psychologists relative to other mental health professionals, with the exception of psychological testing as a distinguishing skill. The unfortunate aspect of the discussion is the difficulty that psychologists have in seeing that the training provided to doctoral-level psychologists is unique among the mental health professionals, not just for the provision of behavioral health care services, but also for the management of behavioral health care systems of care. What most psychologists come to learn in professional practice is that the greatest strength is drawn from all of the subspecialty programs within psychology. Each subspecialty area contributes to a different knowledge and skill base, such as industrial and organizational psychology for the management of health care delivery systems, experimental psychology for the methodology needed to assess the outcome of care, statistical psychology for understanding the meaningfulness of data, social psychology for understanding the impact of social and family systems on the individual, and developmental psychology for understanding the staging process of human development. The list could continue, the profession has yet to prepare graduates to embrace the richness of the field and encourage psychologists to apply themselves to all aspects of the health care system.

There are many forces that will reshape managed behavioral health care. The opening of this chapter addressed the forces at work to create an ever-changing health care environment and those forces will continue to drive the managed behavioral health care organization to evolve to meet the needs of consumers and purchasers of behavioral health care services. The question remains whether psychologists, as a professional group representing multiple subspecialties, find a path for understanding and participation in the evolution of behavioral health care services.

2.35.1 INTRODUCTION

In 1996 there were approximately 20 000 psychologists in the Netherlands, a country which has nearly 15 million inhabitants. Less than one third of them was organized in the Dutch Psychological Association (Nederlands Instituut van Psychologen (NIP)). As far as clinical psychology is concerned, there are two formal professional registrations, that is, the license of "clinical psychologist" provided by the NIP and the license of "psychotherapist" provided by the government, but this situation will change, as will be discussed below. Since 1988, registration as a psychotherapist has been *conditio sine qua non* for registration as a clinical psychologist. Since 1986 formal course requirements and supervised practice have been required in order to be registered as a psychotherapist; since 1989 also for registration as clinical psychologist. The content of these programs are described in this chapter.

The first clinical psychologist in the Netherlands was appointed in 1942. His tasks were limited to diagnostics and he worked under the supervision of a psychiatrist. If there was interest in therapy in the 1940s and 1950s, this was primarily in psychodynamic therapy. With the rise of the nondirective and behavior therapies in the US and in Great Britain in the 1960s, an increasing number of clinical psychologists got involved in psychotherapy in the Netherlands.

There are some studies in the Netherlands which provide figures about the number and characteristics of psychologists who work in mental health settings (Beekman & Heike, 1991; Brunenberg, Neijmeijer, & Hutschemaekers, 1995; Hutschemaekers, Brunenberg, & Spek, 1993; Neijmeijer & Hutschemaekers, 1995; Trijsburg, Duivenvoorden, & Dijkstra, 1988; van Son & van der Staak, 1993). Estimates in this chapter are based on these studies.

2.35.1.1 The Study of Psychology at the University

In contrast to most other countries, in the Netherlands students follow primarily courses in psychology. After approximately one and a half years in which students have to follow courses in all fields of psychology and in methodology and statistics, students specialize in one of the main directions within psychology: developmental psychology, social psychology, psychonomy (general psychology), work and organizational psychology, personality psychology or clinical psychology, and health psychology. For another two and a half years students follow courses in their specialization, have to conduct research in this area, and undertake practice work under supervision.

Eight universities in the Netherlands offer university programs in clinical psychology or health psychology. The total number of graduates in psychology has stabilized since 1990 at about 1025. Clinical psychology has been one of the most popular specializations over the years; 25–30% of the students choose clinical psychology as their specialization.

2.35.2 POSTGRADUATE EDUCATION

After they have graduated from university (i.e., after the first phase of four years), students have several options. Most of them prefer further training in practice or research in the area of clinical psychology, but only few of them actually get the chance to enter one of the formal postdoctoral training programs. This training includes two training programs in clinical practice and one training program in clinical psychology research.

2.35.2.1 Psychotherapy Training Program

Students who want further education in clinical practice have several options. As noted above, until 1998 two formal registrations exist for psychologists working in the field of mental health care: psychotherapist and clinical psychologist. From 1998 this situation will change, as will be described below. First, some information about the contents and the numbers of trainees in the present training programs is given.

Both programs require several years of training after the academic study has been completed. The Psychotherapy Training program involves courses (440 hours) and supervised practice (at least 125 hours supervision over at least 500 hours psychotherapy). Further, trainees have to undergo some form of psychotherapy ("personal therapy," at least 50 hours). This training is accessible for graduates in (clinical) psychology and medicine, provided that they have completed the relevant courses in their university education. Introductory courses in the psychotherapy training program include psychopathology, general aspects of psychotherapy, skills for handling specific situations in clinical practice, systems theory, and introductions to the main psychotherapy orientations: (i) learning theory/cognitive-behavior therapy, (ii) client-centered therapy, and (iii) psychodynamic therapy.

After the introductory courses, students choose one of these three main orientations in psychotherapy. In this area they have to follow two of the following three specializations: children and adolescents, partner/family therapy, and group psychotherapy, both in theoretical work and in supervised practice. The supervised practice must extend over at least four and at most seven years; during this period the trainee must be working for at least two days a week in a mental health institute.

There is no requirement for the psychotherapy trainee to have a salaried appointment for the clinical practice part of the program; in fact, many trainees work as volunteers, while the costs of the courses total up to about $19 000, apart from the costs for personal therapy (about $4000) and the supervision (ranging from US$0 to 8000). Until 1998, no limitations were imposed on the numbers of psychotherapy trainees. In 1996, approximately 2500 people were registered as psychotherapists, while many were still in training. The estimate for 1997 is that 3016 persons will be registered as psychotherapists (Hutschemaekers, Brunenberg, & Spek, 1993).

2.35.2.2 Clinical Psychology Training Program

The Clinical Psychology Training program involves all the elements of the Psychotherapy Training program. Additionally, courses (*in toto* 740 hours) must be followed in clinical assessment, interventions not considered psychotherapy (crisis intervention and consultation, supportive interventions, pharmacotherapy), ethical aspects, and research in clinical practice. In addition to the requirements for psychotherapy training, an additional 140 hours of supervision are required, 70 about psychodiagnostic issues and another 70 about psychological interventions other than psychotherapy and about ethical aspects.

The training is spread over five years, in which students follow courses for one day a week while working in a mental health institute during the other four days. In contrast to the psychotherapy training program, applicants can follow this program only if they have paid employment in a mental health institute. The costs of this program total up to about $28 000, apart from the costs for personal therapy and supervision. In the period 1991–1997, approximately 350 people started the Clinical Psychology Training program.

2.35.3 HEALTH CARE PSYCHOLOGY TRAINING PROGRAM

Changes are taking place in the postgraduate training program. In 1998 the legal registration existed of two basic professions in the field of mental health care: "health care psychologist" and "psychotherapist." The new Psychotherapy Training program will be more or less comparable to the earlier one. However, in the new Psychotherapy Training program, systemic psychotherapy as an additional main orientation is included.

The Health Care Psychology Training program will spread over two years, in which trainees will have to follow courses (440 hours) during one day a week and acquire clinical experience during the other four days. The program is more or less comparable to the first two years of the earlier Clinical Psychology Training program. Some of the registered health care psychologists will be allowed, after completion of their training, to follow further specialization to be clinical psychologist, which will take another three years. For both the health care and the psychotherapy programs, only paid (partly subsidized) training posts will be acknowledged. As a consequence, the numbers of trainees will be drastically limited. In 1998 and 1999, only a total of 82 applicants each year will be allowed to start health care psychologist training and 42 psychotherapist training in the Netherlands.

Apart from these formal training programs, there is a possibility to obtain registration as a member of one of the various therapy associations, such as the associations of (cognitive) behavior therapy, client-centered therapy, psychodynamic therapy, group therapy, etc., but these registrations are not approved officially by the government. One of the "nonlegal" registrations that is becoming increasingly important is registration by the NIP as a "first-line psychologist." These psychologists offer low-threshold brief psychotherapy; a referral via a general practitioner or mental health institute is not required. Gradually more insurance companies pay a (limited) number of treatment sessions provided by these first-line psychologists.

2.35.3.1 Clinical Psychology Research Training Program

The main route to specialization in scientific research is via an appointment as an "assistant in training" ("Assistent in Opleiding" or AIO in Dutch). An AIO is appointed at a university, either for four years full-time, or for five years four days a week. The AIO appointment is a combination of training (including courses) and conducting a research project; in addition, it is customary that AIOs participate in teaching courses in the department where they are appointed.

The aim of the AIO appointment is to conduct, relatively independently, a scientific research project in the area of clinical psychology, resulting in a Ph.D. thesis. A typical AIO thesis consists of four to six (international) publications on a clinically relevant topic, for example, several experimental studies on cognitive processes, attentional bias (in patients and controls), or studies on the etiology, assessment, and treatment of specific anxiety or affective disorders. In the first year of their appointment, the ratio of research to training is supposed to be 55:45, and in the last year 85:15. In practice, most AIOs spend less time following courses than is formally prescribed.

There are no official data available about the numbers of new AIO vacancies; the estimate is that in the field of clinical psychology about 20 postgraduates start this route every year. The AIO appointment offers hardly any possibilities for obtaining formal clinical registrations, although most AIOs are involved in clinical work as part of their thesis.

2.35.4 WORK SETTINGS OF CLINICAL PSYCHOLOGISTS AND PSYCHOTHERAPISTS

In 1996 approximately 1200 people were licenced as clinical psychologists, but many more psychologists work in mental health settings. The chapter will include below figures for the numbers of clinical psychologists and psychotherapists and their respective fields.

2.35.4.1 Psychologists Working in Mental Health Settings

Beekman and Heike (1991) and Brunenberg, Neijmeijer, and Hutschemaeckers (1995) provide an overview of the kind of institutions in mental health care in which psychologists work. Based on these studies, the following estimates have been made of the number of full-time equivalents (FTEs) of psychologists working in mental health care settings (see Table 1).

Table 1 Number of psychologists (FTEs) working in specific settings.

Type of care	*Numbers*
Institutes	
Alcohol and drug centers	20
Psychiatric hospitals	545
Clinical child care: institution	15
Clinical child care: day center	60
Nursing homes	350
Institutes for mental retardates	380
Institutes for deaf and blind, etc.	60
Noninstitutional care	
School guidance	25
Community mental care	900
Centers for alcohol and drug abuse	55
Private practice	480
Other	85
Justice	
Penal institutes	75
Child custody	12

Source: Beekman and Heijke (1991); Brunenburg et al. (1995).

It is, therefore, estimated that 3082 FTE psychologists work in mental health care. These estimates exclude those psychologists working primarily in administrative functions, those who are primarily involved in teaching or research, and those who are employed as a psychotherapist or work in general hospitals (see below). Clearly, not all of the psychologists working in mental health settings are licenced clinical psychologists. The mean age of psychologists working in clinical settings is estimated to be 40 years; approximately 45% are below and 55% are over the mean age. Slightly more psychologists are female (54%) (Brunenberg et al., 1995). Based on the numbers of students enrolled in clinical psychology training programs, it is expected that the number of female clinical psychologists will increase in the future.

2.35.4.2 Psychologists Working in General Hospitals

Since the early 1950s, clinical psychologists have been employed in general hospitals. Although in the early days the emphasis was on assessment, more recently psychologists have been employed in treatment, teaching, and consultation with medical specialists. In 1988, the National Board of Health (Nationale Raad voor de Volksgezondheid, NRV) recommended that in every general hospital at least one psychologist should be employed. In 1995, there were 122 general hospitals in the Netherlands, with a mean of nearly 500 beds per hospital; 101 hospitals (82%) had a department of clinical psychology. The number of licenced clinical psychologists employed in general hospitals was estimated as 194 FTEs. An additional 70 nonlicensed FTE psychologists were also employed in general hospitals: half were trainees in a clinical psychology training program, a few others psychotherapists. In most hospitals clinical psychology is a separate department where clinical psychologists are considered to be "normal" members of the medical staff. Most patients are referred by the department of neurology, followed by the departments of child medicine, internal medicine, psychiatry, and cardiology (Neijmeijer & Hutschemaeckers, 1995).

The figure of the number of psychologists working in general hospitals in Neijmeijer and Hutschemaeckers' study (1995) is less than that in the study of Beekman and Heijke (1991). The higher number of psychologists in general hospitals in the latter study is presumably due to several factors. First, a number of smaller hospitals closed because of government regulations. Second, in the Beekman and Heijke study, psychologists who worked in administrative functions and psychotherapists were also counted as psychologists, which was not the case in Neijmeijer and Hutschemaeckers' study (1995).

2.35.4.3 Psychotherapists

In 1996, approximately 2500 psychotherapists were officially licenced by the Dutch government. Psychiatrists are not included in this figure, since they are not required to be licenced as a psychotherapists. Based on two studies (Hutschemaekers et al., 1993; Trijsburg et al., 1988), the mean age of psychotherapists is estimated as 48 years; nearly 10% are between the ages of 30 and 40 years; 55% are between the ages of 41 and 50 years and 35% are over age 50 years. Approximately half of the psychotherapists are female. Based on the numbers of students enrolled in postgraduate psychotherapy training programs, it is expected that female psychotherapists will outnumber male psychotherapists in the future. Approximately 70% of the psychotherapists have a university degree in psychology (Hutschemaeckers et al., 1993), but this figure will also change in the future. Nearly all students in psychotherapy training programs have a university degree in psychology.

As to the therapeutic schools, most psychotherapists are members of either the association of cognitive-behavior therapy (30%) or the association of family therapy (29%), followed by the associations of group psychotherapy, client-centered psychotherapy, and child psychotherapy. Only 11% are members of one of the three psychoanalytical psychotherapy associations which co-exist in the Netherlands.

Most psychotherapists (60%) work in community mental health centers (RIAGGS); 20% are employed in a psychiatric hospital and 10% in a general hospital. More than half of the psychotherapists also have a private practice (Hutschemaeckers et al., 1993).

2.35.4.4 Relative Numbers of (Clinical) Psychologists, Psychotherapists, and Psychiatrists

Estimates have been made of the relative number of (clinical) psychologists, psychotherapists, and psychiatrists in the Netherlands. For every 10 000 inhabitants there are two psychologists, one psychotherapist, and one psychiatrist available (Brunenberg et al., 1995). The mental health services are spread across the country, but there are relatively more psychotherapists in the western part of the Netherlands where most larger cities are.

2.35.5 JOB PROSPECTS

Until the early 1970s the demands from society equalled the numbers of psychologists available on the market. Nevertheless, at that time gloomy prognoses were given for the future. If one thing has become clear over the past three decades, it is that accurate forecasts are difficult to make. In the 1970s it was predicted that the numbers of psychology students would decrease in the ensuring years, whereas the demands from society were expected to increase. The contrary has proven true. As a consequence, official data from employment offices show increasing numbers of unemployed psychologists: 330 in 1976/77 growing to 1760 in 1985/86 (Van Drunen & Breijer, 1994). Data from employment offices, however, are unreliable. Some authors (e.g., Beekman & Heijke, 1991) have estimated that about half of the those registered as searching for a job are not searching any longer, partly because they had found a job and partly because they had decided to stop searching for work. In addition, these data do not give information about the type of work that is conducted by clinical psychologists, and more specifically, whether they do the kind of work they have been trained for.

Since 1980, several studies have been conducted on demand/supply issues among persons who recently graduated from university. The studies were published between 1981 and 1996, and were reviewed by Brenninkmeijer and Scholing (1996). Most of the studies concerned the graduates from one university only. The percentages of responders varied from 49.4 to 93%. The percentages of persons unemployed varied from 10.2 to 51.3%. The low percentage came from a study with a response rate of 55.1% (Dons, 1992), the highest from a study with a 93% response rate (Dijkstra & Bannenberg, 1986), which might indicate that, in general, nonresponders tend to be more often unemployed. Although the data in these studies lend no clear support for this hypothesis, such selection bias cannot be ruled out.

Beekman and Heijke (1991) studied the job prospects for clinical psychologists in the interval 1990–1995. They estimated the total number of clinical psychologists searching for a job (the recently graduated and the unemployed) at about 4900 for those five years.

Most studies are not designed to reveal trends over the years. Two studies that were conducted at the department of Clinical Psychology in Groningen, however, lend themselves best to a comparison of data over the years, because (i) they refer to students that followed training in clinical psychology at the same university, lived in the same geographical area, in the time intervals 1983–1986 and 1987–1993, respectively, and (ii) almost identical questionnaires were used. The first study of 120 people (Schaufeli & De Vries, 1988) had a response of 75%; of these 78% were employed. The second study, of 250 people (Scholing & Brenninkmeijer, 1995) had a response of 60%; 83.5% were employed. First, it must be noted that in both studies responders were classified as being employed when they had paid work for at least four hours per week. The percentages unemployed are more than twice as high as the mean unemployment rate in the Netherlands (7–8%), but more favorable than the mean unemployment rate of students from other Dutch programs in clinical psychology. The unemployed were over-represented in the recently graduated: from the graduates of 1992 and 1993, 31.5% were unemployed vs. 13.6%, 5.9%, and 11.1% in the years 1987–1989, respectively.

For nearly 36% of the subjects from the Brenninkmeijer and Scholing (1996) study it took at least six months before they got their first paid job; for almost 20% it took at least a year. This implies a slight improvement compared with the situation for the subjects from the Schaufeli and De Vries (1988) study. It seems that it takes some time and effort before new psychologists find a job, but that many of them succeed eventually. In the second study, 30% of the respondents had a full-time job, in contrast with 45% in the first study. This is in line with the general trend in the Netherlands towards more part-time jobs, usually between 17 and 32 hours a week.

The next question concerns the type of work the responders found. In Table 2 a comparison is made between both studies. It shows a shift to more typically clinical work at the expense of research work (mainly at the university).

Table 2 Type of work, in percentages of numbers of responders.

Type	*Study I*[a]	*Study II*[b]
Clinical psychologist	54	68
Research psychologist	16	13
Academic work, but not as clinical psychologist	12	6
Psychologist	8	6
Under academic level	5	5
Other	5	2

Source: Schaufeli and De Vries (1988);[a] Brenninkmeijer and Scholing (1996).[b]

2.35.6 FUTURE DEVELOPMENTS

There are a few areas that will require more psychologists in the future. Most importantly, it is expected that an increasing number of psychologists will be employed in the care of the elderly. Further, an increasing number of psychologists will be working in penal institutes and with juvenile delinquents. Given the relatively few people addicted to hard drugs in the Netherlands, it is not expected that there will be a major increase in the number of psychologists working with addicts. Further, in contrast to most other countries, relatively few people are HIV positive, so special measures to increase the number of psychologists working in this area are not expected.

There are two other areas in which it is expected that there might need to be an increase in the number of psychologists. First, there is a clear need for clinical psychologists to work in firms and factories, for example, providing stress management training. Another growth area is that of behavioral medicine. Given the emphasis in the Dutch health-care system on accountability, it is expected that an increasing number of psychologists will work with stress-related illnesses that were traditionally the domain of medical practitioners.

2.36.1 INTRODUCTION

Clinical psychology has flourished over the past two decades. The number of psychologists in the health service provider subfields has tripled during this time, from approximately 20 000 in 1975 to almost 70 000 by 1995 or about 2500 new doctorates in the health service provider subfields each year (National Science Foundation [NSF], 1996). Equally striking are changes in the "face" of professional psychology. In the 1970s, a newly minted doctorate in clinical psychology would have been white, male, and in his late twenties. More often than not he would have earned a Ph.D. and would be headed, after licensure, toward academic employment or into independent practice. In contrast, today the new doctorate is likely to be a woman and white, although the representation of persons of color has inched up over time. Graduates today are somewhat older than their colleagues two decades ago, with the median age of new Ph.D.s in 1995 at just over 33 years (Henderson, Clarke, & Reynolds, 1996). Increasingly, new graduates may have earned a Psy.D. degree. The new doctorate is less likely to find as many opportunities for academic employment and independent practice as was the case in the 1970s. In fact, clinical psychology may be faced with some tough decisions as it heads toward the twenty-first century, finding work in a system that is searching for the means to confront worsening social problems in light of shrinking financial resources and shifting national priorities.

This chapter begins by discussing the current supply of clinical psychologists and attempts to answer the question "How many are there?" For the most part, this chapter focuses on doctoral-level psychologists, and in some cases, due to limitations of available data, is forced to narrow its focus further on Ph.D. psychologists. However, no discussion of supply or demand can occur without some reference to the supply of master's-level psychological personnel or to the supply of professionals in mental health fields outside psychology.

The next section addresses the demographic characteristics of clinical psychologists, including the gender, racial/ethnic distributions, age, and types of degrees. One of the largest shifts, that of the changing gender composition or the gender "tip" and the implications for the field is given particular attention.

The third section of this chapter presents information about the employment and geographic distributions of clinical psychologists in the USA. What are clinical psychologists doing, in what types of settings and where?

Fourth, the issue of supply and demand is raised. The question of balance is not reducible simply to provider–client ratios but must consider the many recommendations that have urged psychologists to "shift and expand their focus" (Fox, 1994); look at "systems of delivery" (Kiesler & Morton, 1988; Schneider, 1990); explore a "universe of alternatives" (Sarason, 1981); and conduct a "cognitive reappraisal" (Humphreys, 1996). Discussion is worthwhile and, ultimately, encouraging.

The final section incorporates information on the social, economic, and legal milieus in which psychology is embedded and to which the field must respond, and suggests possible future directions for this major subfield of psychology as it moves into its second century. The chapter concludes with a short summary.

2.36.2 HOW MANY ARE THERE?

In order to answer this question as accurately as possible, there must be some agreement about what is meant by "clinical psychologist." As stated in Section 2.36.1, the data are limited to those with doctoral degrees. However, there still is ample room for variability. The answer varies depending upon the purpose driving this question. For example, one may choose to include those with degrees in all health service provider subfields, those with degrees in clinical only, those who are licensed or those with certain degree and licensure combinations. Training in a health service provider subfield does not ensure that the individual is working as a practitioner or provider of health services. Licensure alone does not guarantee preparedness to deliver services and in fact can be used by those with degrees in other psychological subfields such as applied experimental, social psychology or industrial/organizational psychology as an indication of additional "certification" and qualification. This has proven useful to psychologists who are employed in applied or business settings. It is the case that psychologists may be licensed in more than one state and thus may end up being counted more than once in any census activity.

The first count consists of the pool of clinically trained psychological personnel (all those eligible to provide services at the doctoral level). This pool includes:

(i) residents of the USA,

(ii) those with doctoral degrees in clinical psychology as well as other health service provider subfields,

(iii) licensed or not licensed, and

(iv) may or may not currently be providing direct services.

The second count comprises those who are actively providing direct services and consists of US residents with a doctoral degree in a health service provider subfield in psychology, licensed for the independent practice of psychology, and working in psychology as a health service provider. It is important to remember that the majority of doctoral degrees in the health service provider subfields go to clinical psychology and thus the numbers presented here should be highly representative of this specific subfield. Where possible, the numbers are presented separately for the subfield of clinical psychology.

The data for this chapter were derived by using the American Psychological Association (APA) membership numbers and state-by-state data on the number of licensed psychologists. The analyses originally were performed in preparation of a chapter that appears in a National Institute of Mental Health (NIMH) publication called *Mental health United States, 1996* (Peterson et al., 1996). In 1995, there were some 69 817 clinically trained psychologists in the USA. Approximately 76% (53 061) of this number was clinically active. Some 70% of new psychology Ph.D.s in health service provider subfields are granted in clinical psychology specifically (Henderson et al., 1996), which yields an estimate of almost 49 000 trained clinical psychologists and just over 37 000 active clinical psychologists in the USA. These estimates are likely to be conservative since they are based on survey returns rather than census counts and are likely to miss some of the Psy.D. graduates who come from programs outside the accreditation process.

Turning briefly to the master's level, there was a 600% increase in the number of master's-level psychological personnel between 1960 and 1991 (US Department of Education [USDOE], 1994, 1996). The first half of the 1990s witnessed at least 10 000 new master's graduates each year in psychology alone. There were at least 900 terminal master's programs in psychology in 1991 and other data indicate that the number of institutions awarding master's degrees has increased since the mid-1980s (Snyder & Hoffman, 1995; USDOE, 1994). Estimates placed the number of master's-level psychological personnel at 102 945 in 1994 an additional 20 000 by 1996). Data from the National Science Foundation indicate that about 32% (39 342) of the master's graduates were employed in psychology (NSF, 1988). Adding this number to a figure reported in the APA's 1983 Census of psychological personnel (Stapp, Tucker, & Vanden Bos, 1985) yielded approximately 55 551 master's-level psychological personnel working in psychology. At least two-thirds and probably closer to three-fourths of the master's graduates were in the health service provider subfields.

National data reveal two other fields that produced substantially more master's degrees from 1992 to 1993 than psychology. These were counselor education/guidance services in education, and social work (USDOE, 1994), and it is easy to see how the graduates in these fields could be competitors for jobs held by master's-level psychological personnel. Due to changes occurring in the health care delivery system, it also is clear that they could represent a substantial challenge to the full employment of doctoral-level psychologists.

The large numbers of master's degrees granted yearly in psychology, social work, and in counselor education in education; organized psychology's singular focus on the doctoral-level degree as the entry-level degree for the independent practice of psychology; efforts of master's-level providers to organize politically to influence state licensing laws, coupled with shifts in the health care delivery systems and an increasing emphasis on cost containment have pushed the question about the roles and functions of the master's-level psychologist in the provision of health services to the forefront. Increasingly, they are perceived as being in direct competition with doctoral-level providers. This has been called the "master's issue."

2.36.3 WHAT DO THEY LOOK LIKE?

The most obvious shift is in the gender composition of psychology (Pion et al., 1996). Enrolled students and degree recipients at all levels are predominantly female. For example, in 1995, women accounted for 67% of all full-time doctoral students and 74% of full-time master's students in psychology (Williams, 1996). From 1993/94, the most recent year for which data were available, women earned 73% of the bachelor's degrees and 72% of the master's degrees awarded in psychology (USDOE, 1996). Of all new psychology Ph.D.s in 1995, 64% were women, almost doubling the 32% of 20 years earlier (Henderson et al., 1996). The health service provider subfields in psychology have not been immune to this gender tip and it is not surprising that women comprised 44% of the clinically trained pool in 1995, up 5% from 1989 (Dial et al., 1990).

What are the implications of this momentous shift in gender composition, for the field and for services? A thorough discussion of this shift can be found in the Report of the Task Force on the Changing Gender Composition of Psychology available from the Women's Program Office of the APA. Case study findings also were presented in a 1996 *American Psychologist* article (Pion et al., 1996). A summary of the implications addressed in the case study includes the following. The pipeline data indicate that the face of the psychological workforce will continue to change. Rather than imply that these shifts are responsible for any decreases in earnings, or decline in attractiveness or autonomy, the report stresses the fact that the changes that have and are occurring in psychology are the result of external economic and legal forces and not the influx of women into the field.

The representation of persons of color in psychology remained small at about 6% of clinically trained psychologists (Peterson et al., 1996). The population of women was slightly more diverse than was the case for men. The presence of racial and ethnic minorities in psychology was smaller than their representation in the US adult population. Racial and ethnic minorities earned 14% of the Ph.D.s in psychology and 12% of those awarded in clinical psychology in 1995 (Henderson et al., 1996), but they represented 23% of full-time doctoral students in 1995; thus the pipeline is showing some diversification.

The median age of clinically trained psychologists has increased. In 1995 this number was just under 49 years, up somewhat from 1989 when it was just over 44 years. Median years since the doctorate also increased from 12 to 15 years between 1989 and 1995. Generally, women were younger than men and had earned their degrees more recently than men (Peterson et al., 1996).

2.36.4 WHERE ARE THEY FOUND?

The question is interpreted broadly and data are presented for the employment settings and activities as well as for the geographic locations of professional psychologists. In 1995 most of the clinically active psychologists were working full time and at least 50% held two or more positions. Part-time workers were more apt to be working at one position only. Again, most of these data are drawn from the publication by Peterson et al. (1996).

The data indicate that the largest single proportion of clinically active psychologists claimed independent practice as a primary employment setting (52.5%), mostly in individual (41.2%) as opposed to group (11.3%) arrangements. Academic settings were second at 14% and most of the clinical psychologists in these settings were located in higher education (e.g., universities and colleges (11%)), with the remaining 3% in secondary schools and other educational settings. Hospitals were claimed by just over 12%, 6.5% were working in clinics, while nursing homes employed less than 1%. Just over 14% of the practicing psychologists chose a generic "other human service setting" or "other" (see Figure 1).

For the 46% of active professional psychologists specifying a secondary employment setting, independent practice arrangements again were most frequent. Individual private practice was chosen most often (37.4%), while 9.4% specified group practices. Almost 18% were employed in universities and colleges. Hospitals were chosen by 8.9%, clinics by 5.1%, and nursing homes by less than 1%. Schools and other educational settings employed less than 3% and other human service or other settings claimed just over 18%.

A major point of interest in these data is the fact that despite the changes in health care delivery systems, the largest single proportion of practicing psychologists remains in independent practice These findings are supported by data from a 1995 Committee for the Advancement of Professional Practice (CAPP) survey of practicing members of the APA (APA Practice Directorate, 1996) .

Turning from setting to primary activity, just over three fourths of the clinically trained psychologists were involved in patient care and direct service, 9% were teaching, 8% were administrators and 4% were involved in research. Just under 3% indicated some other activity that was not specified (see Figure 2).

The question was asked about extent of involvement in each activity as opposed to primary or most important activity. Again, three-quarters of the clinically trained population was involved in patient care and direct service. This was not a surprise, given the overwhelming presence of professional psychologists in independent practice settings. However, it was interesting to discover that almost two thirds also taught, slightly more than a quarter was involved in administration, and just under one fifth conducted research. The other category climbed to 30% which is sizeable and warrants additional analysis to uncover these activities (see Figure 3).

Taking the setting and activity data together, it appears that clinical psychologists still do consider themselves to be independent practitioners, and that they continue to remain involved in a variety of activities, including teaching, administration and research. The other category is of great interest.

Geographically, where are psychologists located? Regionally, the East and West coasts of the USA held the single largest proportions of clinically trained psychologists, that is, 21% were in the Middle Atlantic region and 17% in the Pacific region. The center of the USA and the South and Mountain regions have markedly lower representation. At the state level, although insufficient to boost the Pacific region on its own to the most populous, California had the highest number of clinically trained psychologists, followed by New York, Pennsylvania, Massachusetts, and Ohio. The same patterns apply to the clinically active subset. A general rule of thumb with respect to understanding the geographic distribution of psychologists in the US is to look to the large metropolitan areas and the areas with numerous graduate programs in professional psychology. The large populations have supported the training programs while the training programs and later, their graduates, have used these concentrations of people for the internships and practices.

2.36.5 ISSUES OF DEMAND: ARE THERE TOO MANY?

When assessing the issue of whether there are too many doctoral psychologists, it depends on what you define as the appropriate scope of practice. It is becoming evident that there likely are a sufficient number of psychologists trained to provide mental health services to individual clients in independent practice settings. At the same time, it is equally evident that wrenching shortages continue to plague other parts of the systems of service delivery. Examples of shortages include rural and frontier areas to which traditionally clinically trained psychologists cannot be recruited and to which they are

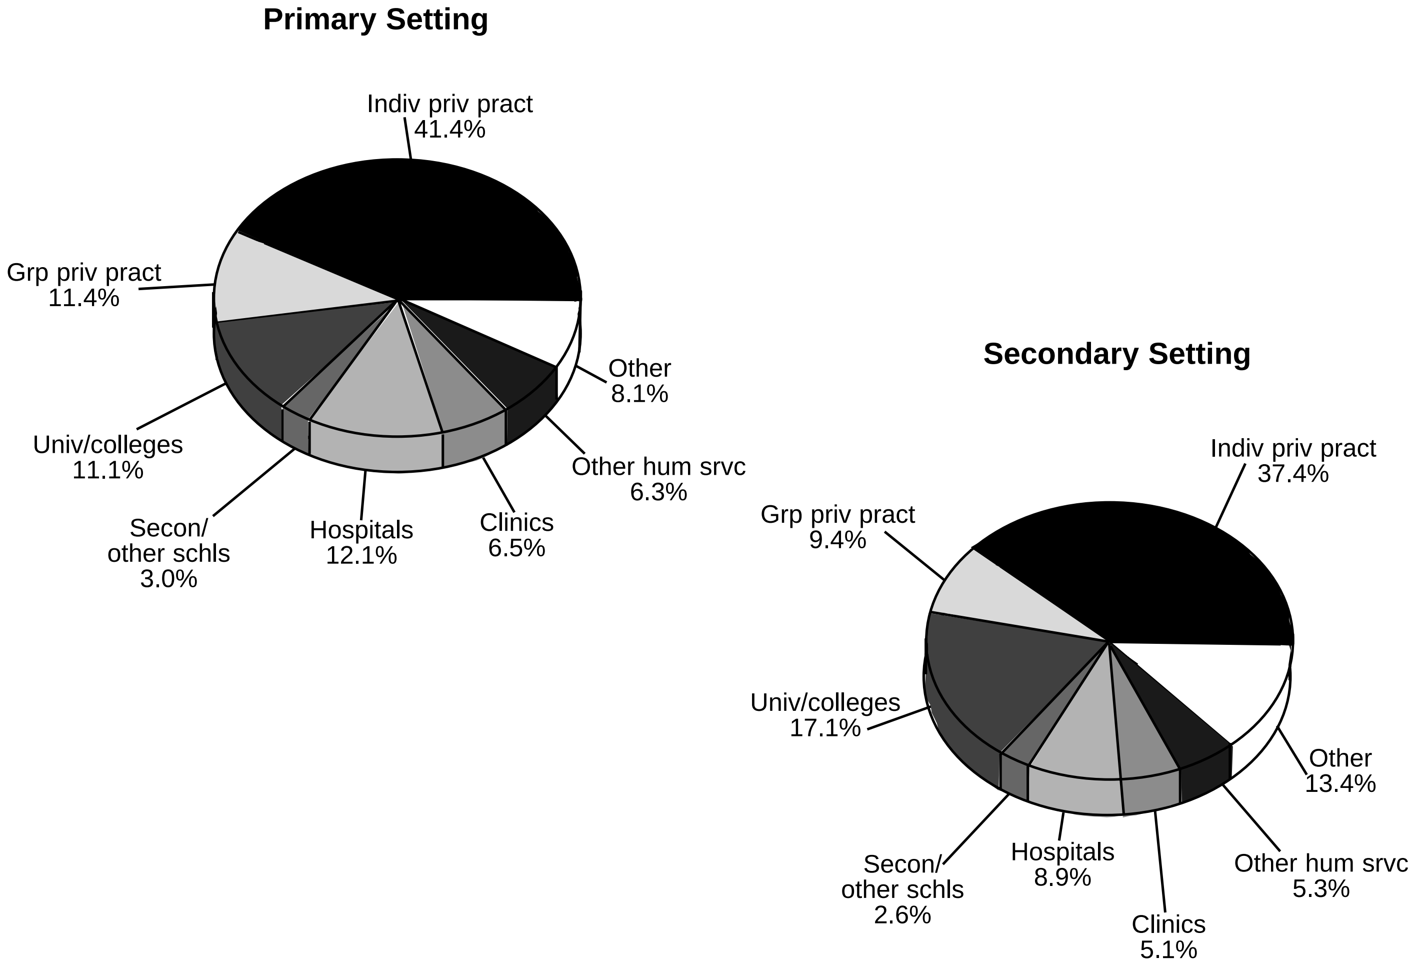

Figure 1 Primary and secondary employment settings of clinically active psychologists: 1995. Note: Percentages may differ slightly from the text due to rounding by the graphics package. Source: Peterson et al. (1996).

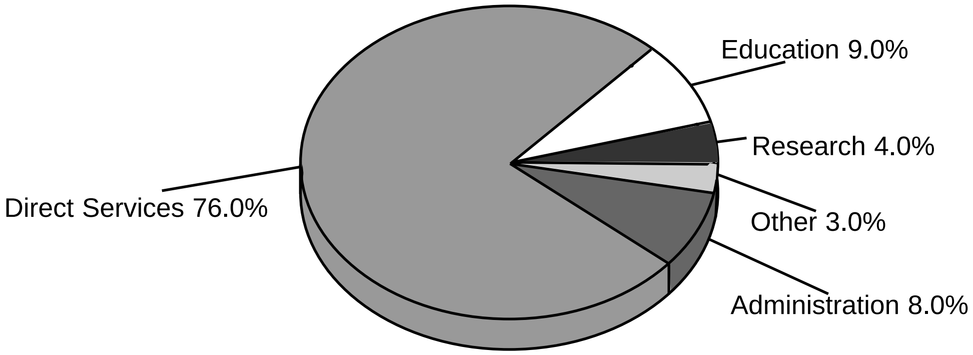

Figure 2 Primary activities of clinically trained psychologists: 1995. Source: Peterson et al. (1996).

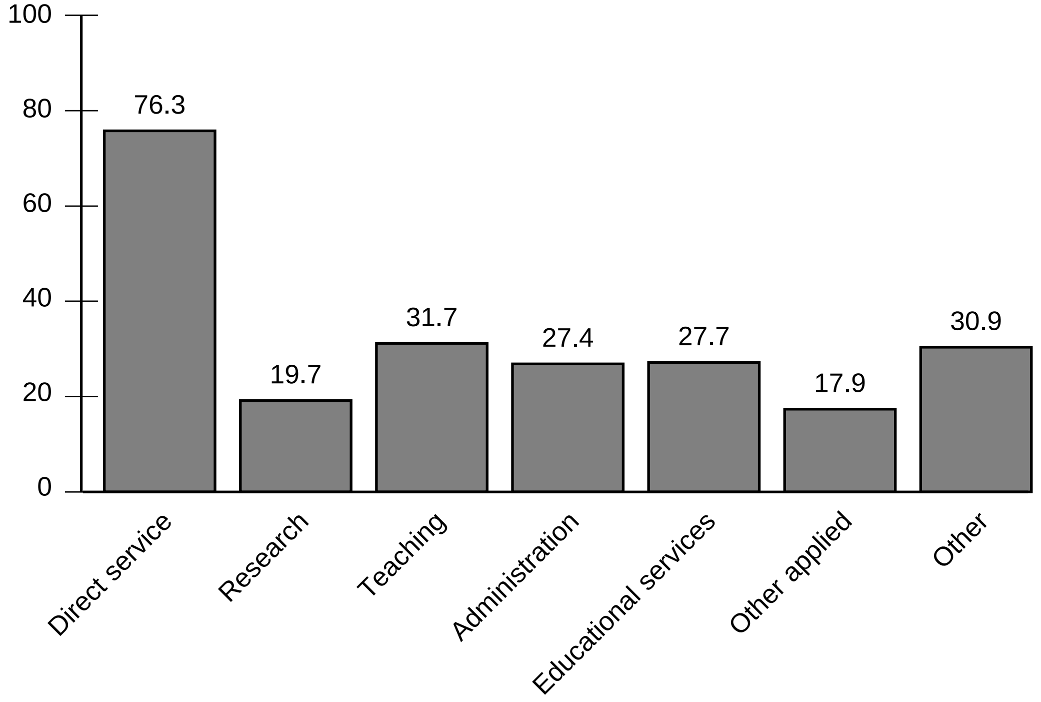

Figure 3 Any involvement in activities, clinically trained psychologists: 1995. Note: Percentages will total more than 100% as respondents could provide more than one response. Source: Peterson et al. (1996).

not attracted. Areas within urban settings that may appear dangerous or not able to support a solo practice also may be underserved. Other shortages can be defined with respect to the clients' needs (e.g., seriously mentally ill adults, seriously emotionally disturbed children, homeless persons, immigrant and minority populations, and the elderly) and organizational settings (clinics, hospitals, state agencies). A common characteristic of these groups of clients, settings, and areas is that they may not fit within the parameters/paradigm of a typical independent practice, and consequently will lack access to services.

Although a perceived oversupply of clinically-trained psychologists and threats posed by the health care revolution to the free practice of psychology may appear to be recent developments, this is not the case. In fact, a number of voices have been raised in common chorus for some time, urging psychology to expand its perspectives on what constitutes an appropriate scope of practice. Sarason (1975, 1981, 1983) has been urging an exploration of the "universe of alternatives" since the mid-1970s. Levy (1984) noted that training and practice in psychology could be more productive if they adopted a human services perspective rather than remaining limited to a focus on the treatment of individual mental health problems. Kovacs (1989) urged that we prepare psychologists to deal with challenges people face across the life span in a variety of settings. In the early 1980s and up to the present, Fox has written and talked about shifting and expanding the focus in professional psychology from an illness driven to a prevention driven model. Kiesler and Morton (1988), VandenBos, Belar, and DeLeon (1991), and Humphreys (1996) have joined the chorus, arguing for a shift to a larger proactive focus on designing systems/interventions/ways to promote healthy behavior and well-being at all levels. Yet, noted Schneider (1990), "it seems that the major practice preoccupations are geared toward a system that is disappearing rather than to the one replacing it."

For the most part the education and training structures in psychology have not changed, and students are not receiving the training they will need to personally succeed in, and effectively contribute to, the evolving health care environment. Despite the many calls for an expansion of the scope of practice and the obvious shifts in health care delivery systems, pessimism among established psychologists and a degree of panic among trainees and new graduates is already evident. At all levels of government and in many business settings, there is a general lack of understanding of what it is that psychologists do and can offer. The depth of understanding appears little better at the level of the individual citizen, where data from the evaluation of the Psychology Traveling Exhibit indicate fairly simplistic and uninformed views of what it is psychologists do. Positively, outcome interviews indicate that people are learning about the variety of research and the practical applications of psychology as a consequence of having attended the exhibit (APA Science Directorate, 1996).

If the educational system does not respond by providing training appropriate to the new health care systems and if clinically trained psychologists continue to establish traditional independent practices in which the client must come to the provider for individual or group treatment, a situation in which the psychologist actually is very passive, it is likely that the judgement will be that there are too many clinical psychologists and that they are irrelevant to the evolving systems and real world problems. This judgement will be held by psychologists, since they will have difficulty making a living, as well as by those responsible for establishing the new systems of health care and by those who are passing the laws and handing out funding for education, training, research, and outreach. The perception of oversupply can be as deadly as actual oversupply, dampening the interest of potential students in psychology as a career and lessening the support for the education and training of psychologists at all levels.

There is no oversupply. In fact, the persistent and worsening nature of many of society's ills and the fact that many of these have behavioral bases lend support to the argument that there are too few clinically trained psychologists. But psychology does appear to have hit a setback in that there is a mismatch between the training that students are receiving and the needs of the society. Suggestions about how to meet these needs is the subject of the next section.

2.36.6 FUTURE DIRECTIONS

Psychology should abandon efforts to model itself after medicine and move toward a proactive and self directing approach in order to define an appropriate scope of practice. This will require the combined efforts of all players within professional psychology. Examples include national, regional and state associations, the education and training structures within psychology, psychologists and students of psychology, and others.

> Professional psychology is that profession which is concerned with enhancing the effectiveness of human behavior. Therefore, a professional psychologist is one who has extensive expertise in the development and application of quality services to the public in a controlled, organized, ethical manner; based upon psychological knowledge, attitudes and skills, in order to enhance the effectiveness of human functioning. (Fox, 1982)

In the future, professional psychology should be prevention driven (Fox, 1994; Sarason, 1975, 1981, 1983) and it should help people to deal with the challenges of daily living across a variety of settings (Kovacs, 1989) and roles (e.g., family, work, parent, etc.). Emphasis is increasing on "designing and implementing interventions that help people pursue healthy behaviors and end or reduce risky behavior" (Humphreys, 1996). Psychology is moving away from a focus on individual-level problems toward the community, social problems, and human services. It will be part of a multidisciplinary effort in many instances in which the psychologist bands together with professionals from other fields to study social problems. The interventions that are designed as a consequence of this elaboration will be stronger by virtue of their multidisciplinary origins.

Defining professional psychology in this way immediately opens up many new avenues for productive and satisfying work. Some of the areas to which psychologists can contribute include human resources management, environmental design, training and supervision, and research on consumer behavior (VandenBos et al., 1991). VandenBos et al. also noted the variety of health related areas in which professional psychologists have made contributions, including: pain management, coping with stressful medical procedures, controlling drug side effects, physical self examination, health monitoring, recovery from illness or surgery, behavioral health, sticking to a health care regimen, and more.

How do we get to this stage? The recommendations that appear below can also be found in the Final Report and Recommendations of the APA Working Group on the Impact of Managed Care and Changes in the Health Services Delivery System on the Education and Training and Continuing Education of Professional Psychologists (American Psychological Association, Education Directorate and Research Office 1996). A copy of this report can be obtained from the APA's Research Office or from the Center For Mental Health Services, Washington, DC.

2.36.6.1 APA Recommendations

The educational system will have to change. Educational institutions will need to target clinical and research expertise to society's real needs (VandenBos et al., 1991). There needs to be greater emphasis on life-long learning and the content and the nature of the training will have to change. Some have called for a common core of general knowledge with specialization occurring postdoctorally. Practical experience or internships will need to be developed outside mental health settings to give trainees some experience with professionals from other fields in a variety of settings. Providing experiences with a diversity of populations and clients will be essential.

Technological literacy is critical to managing one's practice and evaluating and demonstrating effectiveness and efficiency. This involves computer literacy, ability to use information and delivery system technologies and research skills.

The ability to work with and communicate with professionals from other disciplines via interdisciplinary teamwork in multidisciplinary settings will be central to success in the evolving systems. Professional ethnocentrism is to be avoided.

Ultimately, the professional psychologist should be innovative, flexible and able to adapt to nontraditional settings, clients and modes of delivery by offering interventions that have been shown to work.

Practitioners will have to be able to demonstrate the cost effectiveness of psychological services and be able to predict and control costs. They will have to be able to fill public education and advocacy roles and they will need an understanding of the structure of evolving health care systems, including financing, organization, policy, and delivery principles. The ability to market one's services is necessary.

These recommendations and observations from the field indicate that health psychology will have a large role in the future (Cummings, 1995), by providing psychologists with the skills necessary to plan, research, and implement intervention programs for somaticizers and noncompliant chronically physically ill as well as programs for those with unhealthy behaviors (smoking, overeating, etc.) (e.g., Cummings, Dorken, Pallak, & Henke, 1993; Pallak, Cummings, Dorken, & Henke, 1993). Empirical outcomes research is also critical in that it will comprise the basis on which psychological interventions/therapies will rest, most of which are likely to be small group and psychoeducational in nature (Cummings, 1995).

2.36.7 SUMMARY

Clinical psychology has changed noticeably since the 1970s. Post-World War II shifts to a postindustrial society, in which the economy was based largely on the provision of services and an increased dependence on scientific and technical knowledge, brought with it an explosion of opportunities for professional psychology (Howard et al., 1986). The numbers of graduates have grown, tripling between 1975 and 1995 from 20 000 to almost 70 000. Recognizing opportunity, women flocked to psychology. Schools of professional psychology have been established that award a doctor of psychology (Psy.D.) rather than the Ph.D.

Primary employment shifted from organizational or institutional settings to private practice, nudged along by legal changes, increasing acceptance of psychological services and favorable reimbursement policies, and the psychologist was located most often in urban areas, near concentrations of population necessary to support a practice.

Questions about imbalances between supply and demand can be answered a number of ways. If one maintains a fairly limited view of what constitutes practice), then there appears to be an overabundance of practitioners and the supply is greater than the demand. This has negative consequences for the full employment of clinical psychologists. Indeed, data indicate that shifts in the health care delivery system in the USA have had negative impacts on health service providers in independent practice who must try to develop new niches.

Additionally, it is important that organized psychology takes some time to address the master's issue in a reasoned and grounded manner. Perhaps gathering data on the actual content of training at both levels would be a start. Revisiting the frequently mentioned rift between the science and practice of psychology is a needed exercise.

As many have argued, professional psychology must explore alternatives and expand its understanding of what constitutes an appropriate scope of practice. This shift from an "illness" model to a prevention model from a largely passive and reactive stance to one that is positive, proactive and in control—offers many new opportunities for professional psychology. Supply does not exceed demand and unemployment remains low. Above all, the benefits of such a shift extend beyond psychology, to society and individuals, by identifying healthy behaviors and the ways to practice those behaviors.

Although the goal of adopting a prevention approach has been discussed many times and is, from all appearances, a welcome outcome, a critical stumbling block remains. That is that the majority of the education and training systems in the USA have not begun to revise their training to meet the needs of a changing system. As a consequence, students in the health service provider subfields are not learning the knowledge and skills necessary to function effectively in the evolving health care system. The next challenge to reaching the goal of a prevention or human services model is to work with the education and training systems in psychology to design curriculum to meet this need.

2.37.1 THE PUBLIC'S PERCEPTIONS

2.37.1.1 The Impression

Psychology is a broad discipline, but public understanding of its breadth and what it contributes to society is narrow. Psychologists work in so many settings that it is difficult to identify all of them, but the impression of psychologists many people have is limited to them as professors, researchers, or in the traditional counseling and clinical roles.

A national telephone survey conducted in 1995 by the American Psychological Association (APA) (Penn and Schoen Associates, 1995) found that 45% of all respondents believed that psychologists "generally help people with problems or offer counseling." Others (30%) said that psychologists "analyze people or study human behavior" (see Figure 1).

While it is true that many psychologists engage in clinical and counseling work, the world of psychology is much broader than the public often realizes because the work of psychologists in other settings occurs under other job titles and identities.

2.37.1.2 The Reality

Since the domain of psychology is the study of human and animal behavior, there are very few areas of inquiry which are not of interest to psychologists. In fact, psychological skills and

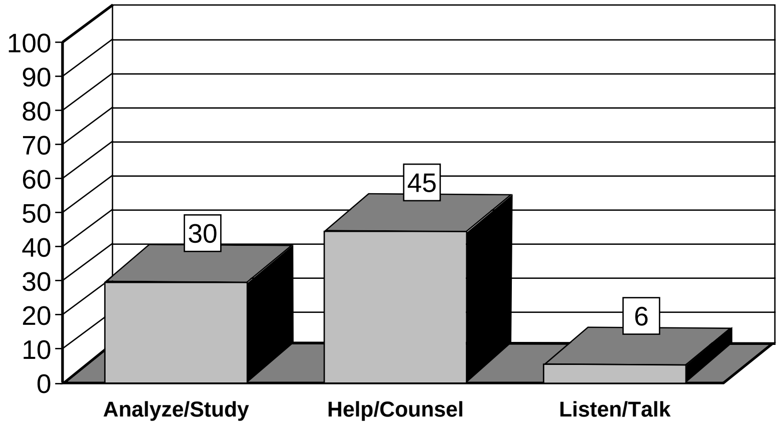

Figure 1 What Do Psychologists Do?
Source: American Psychological Association.

knowledge are relevant to a broad segment of social problems and public policy issues, for example, aging, AIDS, violence, depression, and drug abuse.

Today approximately 80 000 doctoral level psychologists (about half of the psychologists in the world) live and work in the USA. They work in a number of major subfields including clinical psychology, counseling psychology, developmental psychology, educational and school psychology, forensic psychology, health psychology, industrial/organizational and engineering psychology, neuropsychology, quantitative and measurement psychology, rehabilitation psychology, and social psychology. The first two subfields, clinical and counseling psychology, are somewhat familiar to the general public (although studies show that the public has very little understanding of how to differentiate among mental health providers). The remaining subfields, research shows, are unfamiliar to most members of the lay public.

Exact reports of how many professionals work in each of the subfields are difficult to ascertain because many in the field work in more than one role (see Figures 2 and 3). It is estimated however that approximately 20% of the discipline are in academic positions teaching and conducting research. Approximately 50–60% are thought to be primarily engaged in health service delivery (APA, 1996a).

2.37.2 THE HIDDEN CONTRIBUTIONS OF PSYCHOLOGY

There are numerous places where psychologists and psychological data collection and analysis are making contributions behind the scenes (e.g., social welfare, health and medicine, education, and corporate competitiveness) but are unknown to the general public. Some examples are:

(i) *Computer technology*. The computer and electronic communications revolution has benefited from, and continues to need, the input of psychologists. Computer learning and communications require that people learn to use the systems and function comfortably at them. Psychologists help in the design of teaching tools as well as operating systems and work stations that match human minds and bodies. Social psychologists also study the effect that communications via satellites and circuitry rather than face-to-face have on society and the way human beings interact.

(ii) *The new American demographics*. Towards the twenty-first century the world is a smaller place. America is more culturally, racially and ethnically diverse then it has ever been before. Psychology has a role in understanding the needs and ramifications of a more diverse population and helping institutions from governments to business to schools adjust to this new reality.

(iii) *Corporate downsizing*. Industrial/organizational psychologists and engineering psychologists teach corporations and business leaders to do more with less and deal with international economic challenges by finding work efficiencies, streamlining production processes, and promoting good management of human resources.

(iv) *Education reform*. Psychologists study the teaching and learning process and work in schools to make them more effective.

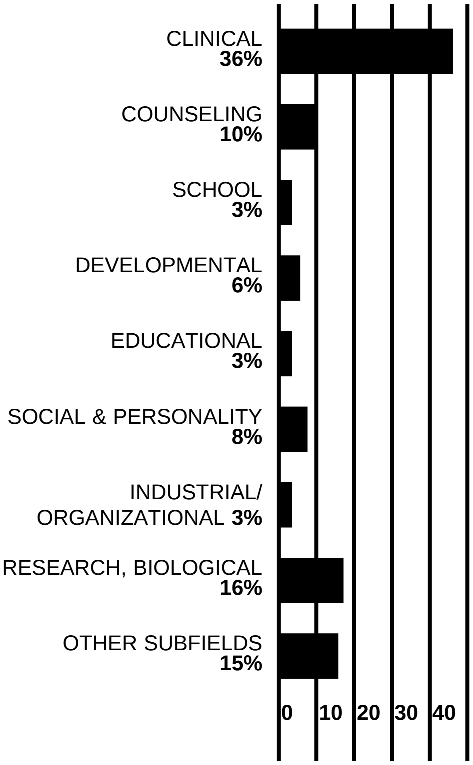

Figure 2 Subfields doctoral psychologists enter. Source: Adapted from 1993 *Survey of Doctorate Recipients*, National Research Council and National Science Foundation, Washington, DC.

2.37.3 THE WORK OF PSYCHOLOGISTS IN NUMEROUS AND VARIED SETTINGS

2.37.3.1 Psychologists in Healthcare Settings

It is estimated that between 50 000 and 60 000 psychologists work in a wide range of healthcare settings such as hospitals, clinics, in individual private practice, and as members of teams of primary care providers. Health psychologists study how biological, psychological, and social factors affect health and illness. In the last two decades clinical psychology has made large strides in evolving from a mental health profession to a health profession that teams with other healthcare providers—from primary care physicians to disease specialists—to provide comprehensive healthcare for patients. While most health disciplines specialize in the physical aspects of illness, psychologists are expert in the behavioral aspects of illness and the coping and adjustment skills needed to recover from illness. The connection between the mind and the body is well-established. Health psychologists understand how emotional illness can have physical ramifications and apply that knowledge to help people get well and stay well.

Psychologists begin to make important contributions to a patient's health at the initial stages of care giving. Psychologists evaluate patients by assessing personality traits and cognitive and motor abilities (memory or reaction time, for example). They work with other specialists to design and implement treatment plans to improve those skills.

Psychologists also help patients deal with the stress or discomfort which can be caused by the medical care, and play a critical role in keeping patients to their treatment regimes and recovery. Cancer patients, for example, often consult psychologists for help with medical decision making, treatment compliance, and the stress and depression that can accompany a cancer diagnosis.

Health psychologists also have an important role to play in preventing illness. They investigate health problems that affect large segments of the population such as smoking, sexually transmitted diseases, and poor diet. They can then design interventions to deal with these problems.

Research has shown that approximately half of all visits to primary care doctors are for symptoms for which psychological rather than physical causes are primary. The health psychologist in the USA therefore has a critical role to play in both the well-being of the American public and in reducing national healthcare expenditures.

Some psychologists have extensive training in psychopharmacology and work closely with physicians in determining appropriate medication for patients. Many psychologists believe that expanding their clinical skills to include prescribing drugs will allow them to better treat their patients. In a 1995 poll of its membership, the APA found that 62.7% of its members agreed with the statement, "appropriately trained psychologists should prescribe medication." Of the membership, 33% disagreed with the statement. No states currently license psychologists to prescribe drugs, but it is being considered by a few state legislatures.

Those who argue for prescription privileges believe that psychologists who prescribe will be better able to provide complete care for patients and will be able to appropriately coordinate medications with the psychotherapy needs of the patient. Opponents of prescribing, however, worry that the need to keep up with new advances in psychopharmacology will rob psychologists of the time necessary to continue to develop their expertise in psychotherapy.

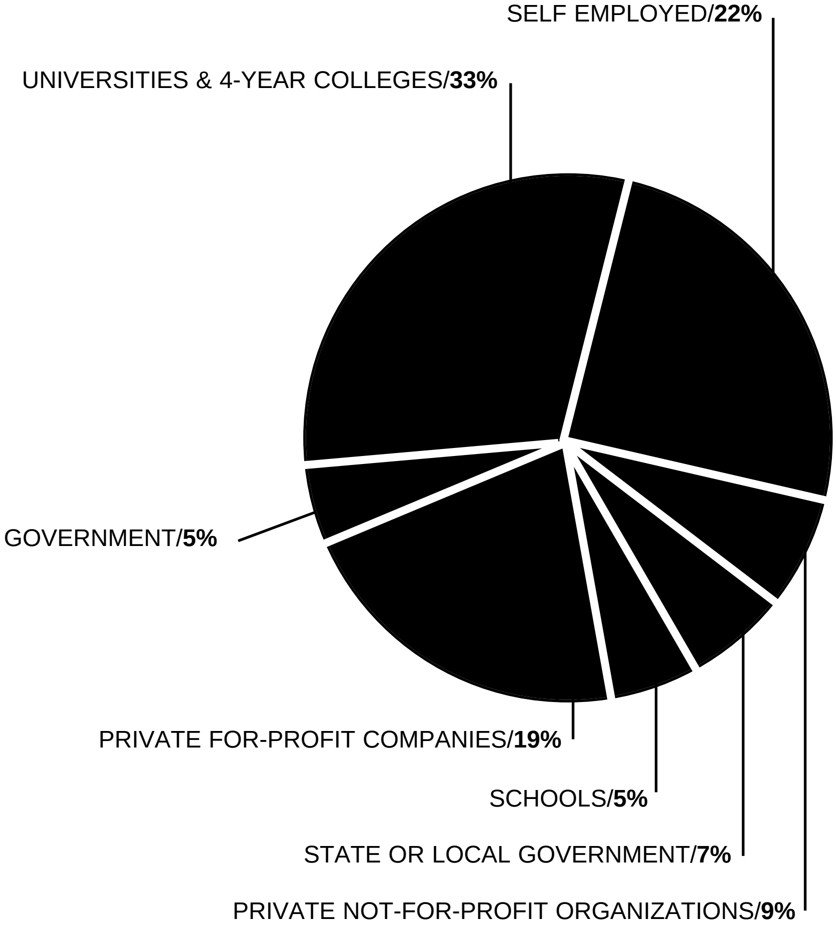

Figure 3 Where doctoral psychologists work.
Source: Data for psychologists working full time for others adapted from *Survey of Doctorate Recipients*, National Research Council and National Science Foundation, Washington, DC. Individual and group practice data are from Research office, APA Central Programs.

Up to 1997, four psychologists have graduated from a special military training program created to test the value of prescribing privileges for psychologists working with military personnel and their families and have been authorized to prescribe drugs. After some initial conflict with their military colleagues in the psychiatric ranks, all report good working relationships with other military doctors. Seven additional psychologists are in the training program in 1997.

2.37.3.2 Public Health Programs

Psychologists are tackling some of the late twentieth century's most troubling public health issues by both studying their root causes and designing interventions to solve them or help people cope with their ramifications.

Psychologists have been at the forefront of the battle to defeat AIDS since the epidemic was first identified. Psychologists are studying how to educate and motivate AIDS patients and those at high risk of contracting the virus to protect themselves against becoming infected. Needle exchange programs, for example, have been studied by many researchers. Psychologists also help patients and their families cope with the challenges of living with AIDS/HIV (Clay 1996; Sleek 1996).

Substances abuse is a problem that robs many people of their livelihoods, families, and even their lives. Psychologists, many specializing in the treatment of drug and alcohol abuse, treat patients with substance abuse. Research psychologists also study why some people become addicted to a substance while others do not, as well as what treatments programs have the greatest success rates.

Violence is a universal problem in the world. Violence takes places in urban centers, in rural communities, in the workplace, and at home. Psychologists have both studied the causes of violence and designed interventions to prevent it. In the workplace, psychologists theorize that violence often erupts as the results of unchecked stress and rage within an employee, but find it difficult to predict who may become violent in the work setting. Psychologists who study workplace violence have found that losing one's job is a better predictor of violence than age, gender, socioeconomic status, ethnicity, or diagnosable mental disorder. But, evidence does show that those who become violent often have a history of aggression, poor self-esteem, are socially isolated, and blame others for their problems (Martin, 1994).

Family violence is another area that psychologists have studied and work to prevent. Violence among family members is not restricted to any cultural or economic groups, but through research, psychologists have ascertained that family violence is circular—that it is passed from generation to generation within a family. Children who are abused and who witness adult members of the family hitting each other are more likely to be both the perpetrators and victims of violence as adults.

Psychologists intervene with families that are having trouble with domestic violence in numerous ways. Often helping people acquire better life skills, such as parenting skills and job skills, will help lessen the violence problem. A program in which psychologists make repeated home visits to families who are experiencing problems with violence has been found to be particularly effective in stemming that violence. The full involvement of many community resources in coping with the family violence problem has also proven to be very important (APA, 1996b).

2.37.3.3 The Workplace

Psychologists can be found in the workplace under a variety of job titles from human resources manager to quality performance director to wellness manager to consultant but most are there with the same basic mission; to make the workplace productive and safe.

Businesses today face numerous human resource challenges; getting the right employee in the right job, getting employees the training they need, making the workplace safe and keeping employees healthy, making the production process (whether the product is a widget or intellectual property) efficient, and keeping non work-related problems from interfering with employee performance.

Psychologists study, design, and implement intervention strategies to keep workers reporting to work healthy, ready to work, and to keep business moving ahead.

Clinical psychologists are also branching out into the fairly new subfield of executive coaching; working with corporate executives to strengthen their management, leadership, and interpersonal skills. Often both corporate leaders and line managers do not have a sufficient understanding of employee morale needs and how to build high functioning workplace teams and resolve conflict. Psychologists teach these skills where needed.

Workplace issues are likely to remain a strong area of work opportunities for psychologists. It is estimated that the direct and indirect costs of stress-related disorders to business in the USA now stands at $100 billion annually. Furthermore, about 600 000 workers a year are disabled by psychological disorders.

2.37.3.4 Forensic Psychologists

Forensic psychologists work within and for the justice system and attempt to bring psychological knowledge to bear in the search for justice and equitable outcomes in court cases. Psychologists who work in forensic psychology often interview defendants at the request of defense attorneys or the court to judge their competency and state of mind. Psychologists are typically involved in divorce and child custody cases usually offering an opinion about the developmental and emotional health of any children involved in the case.

Other psychologists study jury behavior and help attorneys select juries who will be most likely to side with their clients.

2.37.3.5 Human Factors Research

Designing machinery and manufacturing processes to fit comfortably with the labor force is the expertise of human factors and engineering psychologists.

Human factors psychologists also study human performance and match the limits of human performance to work demands. For example, psychologists working in the NASA Fatigue Countermeasures program are developing a means by which to measure pilot fatigue and its effect on performance. Concerns about pilot alertness especially during long transmeridian flights were first raised in the early 1980s. Today, psychologists working on or with the NASA team use basic behavioral research on sleep physiology and circadian rhythms to design instruments that measure alertnes and performance. They have also taken these instruments into the cockpit to test general theories and countermeasures where pilots actually work (Azur, 1996b).

This research has concluded that allowing pilots to rest during long flights can improve their alertness at the end of that flight. Findings from this research will have important cross over into many other fields that require around the clock schedules such as law enforcement, public safety, and medicine.

Another area in which psychologists are working behind the scenes to protect the public is in the design of medical devices. The US Food and Drug Administration (FDA) must approve all medical devices; FDA approval is based on product safety and effectiveness, although not whether the product is user-friendly. However, these devices are often used by staff in busy hospitals, who are working on severe time constraints, heavy workloads, and at times fatigued.

An added emphasis on good human factors engineering in the design of medical devices began in the early 1990s when the FDA started to ask why so many well-trained professionals were failing to use them properly. Psychologists who work in the area point out that as medical devices become more complex and as more and more healthcare takes place in the home or some other out-of-hospital settings making medical devices more user-friendly is more critical than ever (Azur, 1996a).

2.37.3.6 Psychologists in Schools

Schools mirror the communities in which they exist. Today they are asked to teach children in increasingly difficult circumstances. Psychologists, both by studying the teaching and learning process and by working in schools directly with administrators, teachers, and students, are helping schools fulfill their mission.

School psychologists bring health and social services into schools or expand those services which already exist. Such programs involve a holistic approach to problems which do not have simple solutions such as substance abuse, youth violence, or teenage pregnancy. For school-based health programs to be effective they must be appropriate to student ages and development levels. As schools move to meet the health needs of their students, psychologists are able to help with program design based on their knowledge of how children grow and develop. Psychologists, for example, have studied why teenagers join gangs or take health risks and can therefore develop strategies that will effectively deal with these circumstances.

Many school districts employ psychologists full-time. In other school districts, psychologists are consultants to administrators and teachers.

Educational psychologists concentrate their work on the study of how effective learning and teaching take place. They consider a variety of factors, such as human abilities, what motivates students, and the effect on the class of the diversity of races, ethnic, and cultural backgrounds that makes up most school populations.

The basic question which educational psychologists have sought to answer is what motivates children to learn and what is detrimental to that learning. Psychologists have found that much of the answer lies in showing students the personal stake they have in the learning process and in giving them choice and personalization in their work assignments.

2.37.3.7 Military Psychologists

The work of psychologists has long helped the military improve training programs and study the effects of military operations on soldiers. For example, psychologists completed a large scale study, involving over 10 000 Gulf War veterans, which examines the impact on soldiers and reservists of rapid mobilization, leaving home and family life, as well as exposure to combat and other war-related stresses. Results from this study convinced the US military to make mental health services more available for American troops when they were deployed into Bosnia in December of 1995. Thirty-seven percent of those soldiers interviewed in the Gulf War veterans study were diagnosed with a psychiatric condition, most commonly either depression (11%) and posttraumatic stress disorder (5%).

As it becomes more common for military troops to be called to international trouble spots to act as peacekeepers, psychologists are studying the psychological stresses involved in that assignment which often includes dealing with strict rules of engagement, a hostile local population, and scores of displaced persons.

2.37.3.8 Psychologists Study the Media

Psychologists were pioneers in studying the effects that television would have on its viewers, especially children. Psychological research done over the since the 1950s has shown that children who watch a lot of violent programming on television are:

(i) less sensitive to the pain and suffering of others,

(ii) more fearful of the world around them,

(iii) more likely to behave in aggressive or harmful ways toward other people (APA, 1991).

In the late 1990s, psychologists are at the forefront of the study and applications of the Internet and other forms of electronic communication and information exchange. Psychologists, for example, want to know what effects the Internet will have a person's ability and desire to deal with people on a face-to-face basis. Is teaching over the Internet an effective way for children or adults to learn? These are questions which psychologists who study the media and new media technologies are investigating.

Clinical application of new media technologies is an area of controversy within the profession. The Internet is an example of a new communications technology with numerous potential applications in the mental health arena.

Does psychotherapy via the Internet have value? Is offering therapy via the Internet an ethical thing for a provider to do? Some proponents of psychotherapy via the Internet say that for people who live in rural areas or for other reasons can not get to a mental health provider's office, help through the Internet is better than no help at all. Others say it is valuable as an adjunct to an occasional face-to-face sessions. However, some observers believe that the Internet is a poor replacement for traditional psychotherapy.

2.37.3.9 Sport Psychology

At the 1996 Summer Olympic Games in Atlanta few individual athletes and teams went into the competition without having first worked with a sports psychologist. Two high profile events, women's gymnastics and track and field, especially benefit from the attention of sports psychologists. Both events demand supreme concentration and put years of training and preparation into a few minutes of performance which will separate victory from defeat.

Psychologists who work with athletes help them refine their focus on competition goals and motivation. They also help athletes deal with the anxiety and fear of failure that often accompany competition.

Ground-breaking research by sports psychologists has shown that quality training and mental preparation for competition were the two consistent elements needed for Olympic caliber success. Quality training was characterized by intense focus during practice, clear daily goals, imagery training to perfect skills, athletes who imagine success, prepare for training, and motivate themselves. Mental preparation for competition included having a precompetition plan, having a competition focus plan, evaluating the lessons of competition, and controlling distractions.

2.37.4 FUTURE DIRECTIONS

As the twenty-first century approaches a few demographic realities are clear. The population of the industrialized nations is aging, the world population continues to grow, and the American population is more diverse than ever. Psychologists will have important roles to play in the study and application of knowledge to help individuals and society as a whole cope positively with these changes.

In 1992, the last year for which data is available, 3373 doctorates in psychology were awarded by universities in the USA. Of these graduates 46% said they would pursue work in clinical and counseling psychology and 16% planned to pursue work in psychological research; the rest varied widely. These newcomers to the discipline will comprise the psychology workforce of the twenty-first century. It may also be important to note that during 1992 63 513 students earned their bachelor's degree in psychology and another 10 215 earned a master's degree in the field (Wicherski & Kohout, 1995).

Psychology continues to be a very popular undergraduate major, ranking second as the most common major for undergraduates on many campuses. About 5% of these new bachelors degree holders go on to earn their doctorate. Others join such job fields as social services, sales and service personnel, business management, engineering and computer science (see Figure 4).

Since the 1890s, psychology has grown dramatically and made important contributions to society. The next 100 years holds the same potential for the discipline.

2.38.1 INTRODUCTION

The reach and impact of television and films are unquestioned. Of all American homes with children, 99% own at least one television. Movies have been popular leisure time entertainment since the 1930s.

In their book, *Tuning in trouble: Talk TV's destructive impact on mental health*, psychologists Heaton and Wilson (1995) write that "television is at the heart of American culture; its power and influence are unparalleled."

About movies, Sklar (1994) writes in his book *Movie-made America*,

> ever since the peep shows first captivated urban audiences, film has had a revolutionary impact on American society transforming culture from the bottom up, radically revising attitudes toward pleasure and sexuality, and at the same time, cementing the myth of the American dream.

Many professions have been created in the public's mind through their portrayals in film and on television. For a generation of Americans, Marcus Welby set the image of what their family doctor should be. In the 1960s Perry Mason set the image of the laconic lawyer who fought for justice and always got to the truth. That image has been greatly changed by later television portrayals of lawyers on such hit shows as *LA Law* and *Murder One*.

People such as Bob Newhart, Woody Allen, and Nurse Ratched in *One Flew Over the Cuckoo's Nest*, have combined many characters to create the public image of the therapist and the patient; an image that in the movies and on television has revolved more around dysfunction than improved functioning.

Research has shown that the public's ability to differentiate between different types of mental health providers is poor (Woods, Jones, & Benjamin, 1986). What role did the media play in this lack of understanding? There are numerous examples of the media's stereotypical portrayal of mental health professionals. There are also numerous examples of the often poor job the media has done in portraying the therapeutic relationship.

During the 1930s numerous films featured a psychiatrist character. All had central European accents, were comical figures, and often appeared to be in need of treatment themselves. The actor Fritz Feld created the mold with his portrayal of a psychiatrist (complete with a facial tic) in *Bringing Up Baby* (1938).

In the 1947 classic, *A Miracle on 34th Street*, the character Kris Kringle is challenged by the Macy's store psychologist who pronounces Kris "dangerous and psychotic." Again however, the protagonist outwits the mental health provider, a small and nervous man who twists his eyebrows incessantly. This was "therapist as villain" movie-making. When an elderly man believes himself to be Santa Claus, eventually even the lawyers see his humanity and goodwill and begin to root for him. The villain of the film is the psychologist hired to screen new employees, he is a bundle of nervous habits and odd behavior—paranoid and downright mean.

In the 1958 film, *No Time for Sergeants*, Andy Griffith plays a Georgia farm boy who joins the air force and outwits the military psychiatrist. "Well I reckon I love my mother," Griffith tells the psychiatrist. "Don't you love your mother?" he then asks, evoking anger from the doctor.

The 1960s hit television sitcom *I Dream of Jeanie* featured a NASA psychiatrist, Dr Bellows. Poor Dr Bellows was always in a state of befuddlement as the other main characters, Jeanie, Roger, and Major Nelson, hide Jeanie's true identity (see Figure 1).

Probably the most far-reaching of all the television and film characterizations of psychologists and psychiatrists is the television sitcom of the early 1970s, *The Bob Newhart Show*. The Newhart show was extremely popular and held the Saturday evening time slot. The protagonist, Bob Newhart, a psychologist, was a caring but ineffectual therapist. A stream of patients came in and out of his office, each more strange and dysfunctional than the last. This one show, the only network show of the time featuring a psychologist as one of the main characters, left an indelible impression in the TV viewing public's mind—the psychologist as the middle-aged man in a now wildly out of style polyester suit, kind, but bumbling and unable to do much of anything to help his patients cope with their problems. His patients were an odd collection of neurotic souls—caricatures of people rather than real people. A virtual parade of dysfunction on both sides of the therapeutic relationship.

The cable television network, *Comedy Central*, has created a modern day psychotherapist as sitcom example, *Dr Katz: Professional Psychotherapist*. The show's producers describe it as an animated TV show about the funny, lovable psychotherapist who people love to take advantage of. The fact that this show is animated is somehow fitting with the way that the entertainment industry has treated and continues to portray the profession.

The best-selling novel by Pat Conroy and later a hit movie (1991), *The Prince of Tides* created a new portrayal of the psychiatrist—different from earlier characterization but also troubling. In the movie, Barbara Streisand plays a competent, compassionate, very human professional, but one with questionable ethics. The story line takes the Streisand character from psychiatrist to the main character's lover. The problem is the main character, Tom Wingo, who is also the brother of one of Streisand's current patients.

2.38.2 WHAT HAVE ALL THESE IMAGES ADDED UP TO CREATE?

The question is, what effect have these negative and inaccurate portrayals of psychiatrists and psychologists had on the viewers' psyche and health consumer behavior? The provider-character who is "crazy," strange, befuddled, and ill-tempered gets the most laughs and is most common. But is it educative and reassuring for the viewing public?

What has been the effect of the media portrayal of psychologists and other mental health providers? Many studies have shown that the public is not well educated when its comes to mental health issues nor types of mental health specialists. Americans are unsure as to how psychotherapy works and what psychologists and psychiatrists actually do.

In 1994, the American Psychological Association (APA) conducted both a national telephone survey and consumer focus groups to ascertain the public's attitudes towards and understanding of mental health issues and providers. Some important results were as follows:

(i) The public is nearly universally unable to differentiate between the different types of mental health providers.

(ii) Few people understand the educational and licensure requirements to practice psychology. Just 36% of those asked know that a doctoral degree is required to be a psychologist. Additionally, one in five believed that psychologists need a medical degree to practice; these data may reflect people confusing psychologists with psychiatrists.

(iii) Finally, there exists a great deal of confusion about the best way to evaluate and select a mental health provider.

A summary of the findings of the national focus group series reported the following,

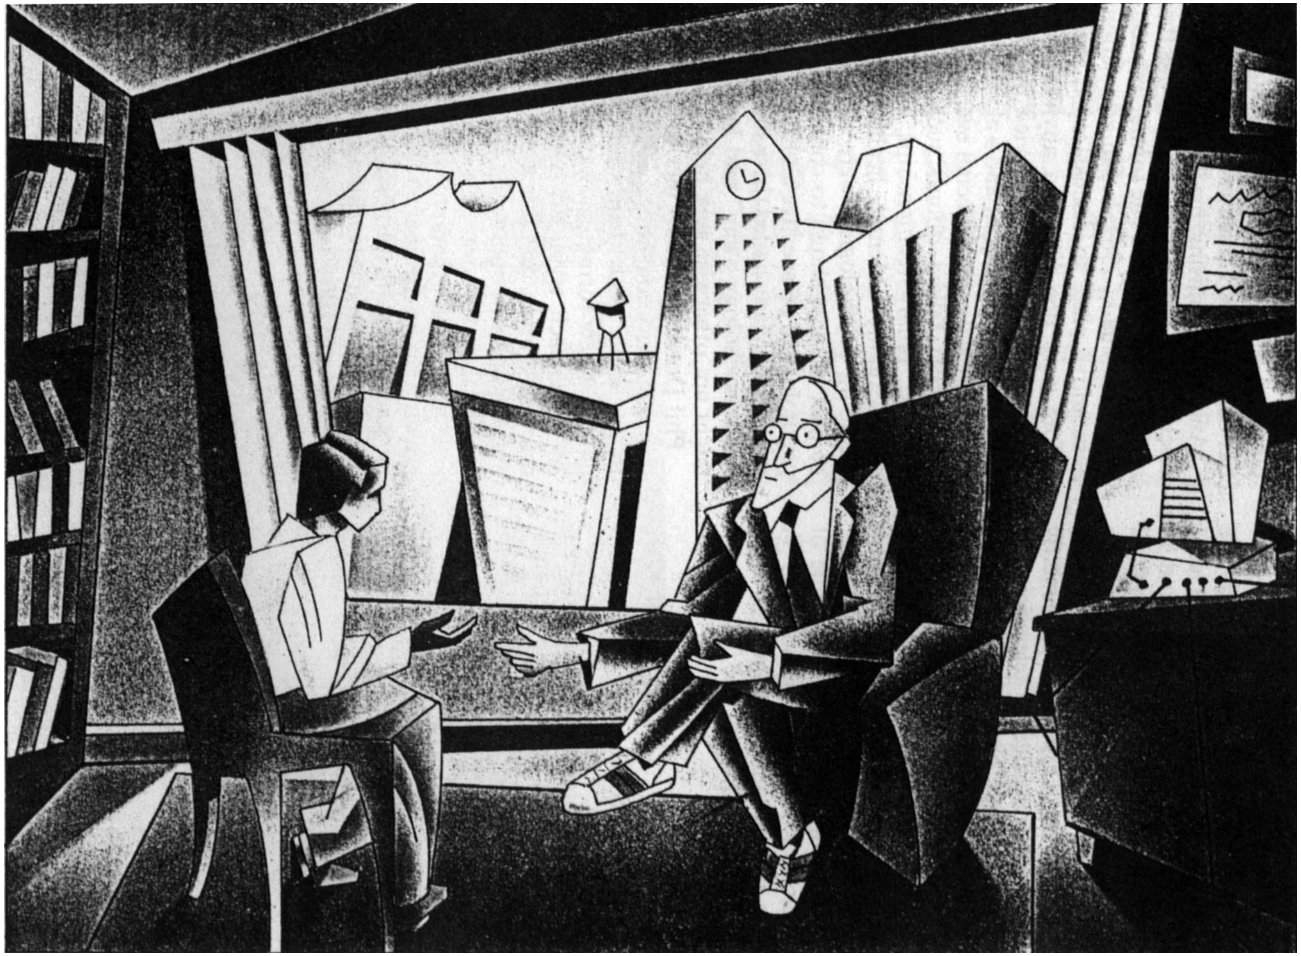

Figure 1 The media often portrays therapists as characters and humorous figures (Source: APA).

"across all the groups there was general confusion about the differences between the various types of mental health care providers. Most had limited experience in using or being exposed to mental health care services. Some made comments about the images of such professions being based on what they had seen in the media, particularly talk shows and programs like *Bob Newhart*."

Another focus group finding was that the term "mental health" was actually associated with "mental illness" by most people and to these people mental illness meant "being crazy."

This research also identified five primary barriers which prevent people from seeking psychological services. Three seem particularly related to the images created by television and movies—concerns about the treatment outcome (43%), the length of treatment (26%), and about how seeking treatment will affect their career (26%).

Where does the public get the impression that psychotherapy treatment would go on for indefinite lengths of time and the outcome of all of this time would be questionable? A Woody Allen movie comes to mind! "I don't think you ever get cured," said one focus group participant.

2.38.3 WHAT IS LOST?

Have the wrong impressions of the therapeutic process that the public has had an effect on its mental health? Data, again collected by APA, suggests that they have.

The APA found an information gap when it did public attitudes research. Most people knew that psychological health is important to ones' overall well-being, but did not feel that they knew when it was appropriate to seek mental health services or how to go about selecting a provider.

Of even greater concern than a lack of information is the negative impression that the media's handling of the mental health profession has given the public. Research has shown that the therapeutic set, the concept that if the client believes the therapist to be an expert in psychological techniques the client will improve, holds (Turkat, 1977). The question is, if the public generally believes that mental health professionals are incompetent how does that interfere with the therapeutic relationship?

2.38.4 THE TELL-ALL AND TALK SHOW PHENOMENON

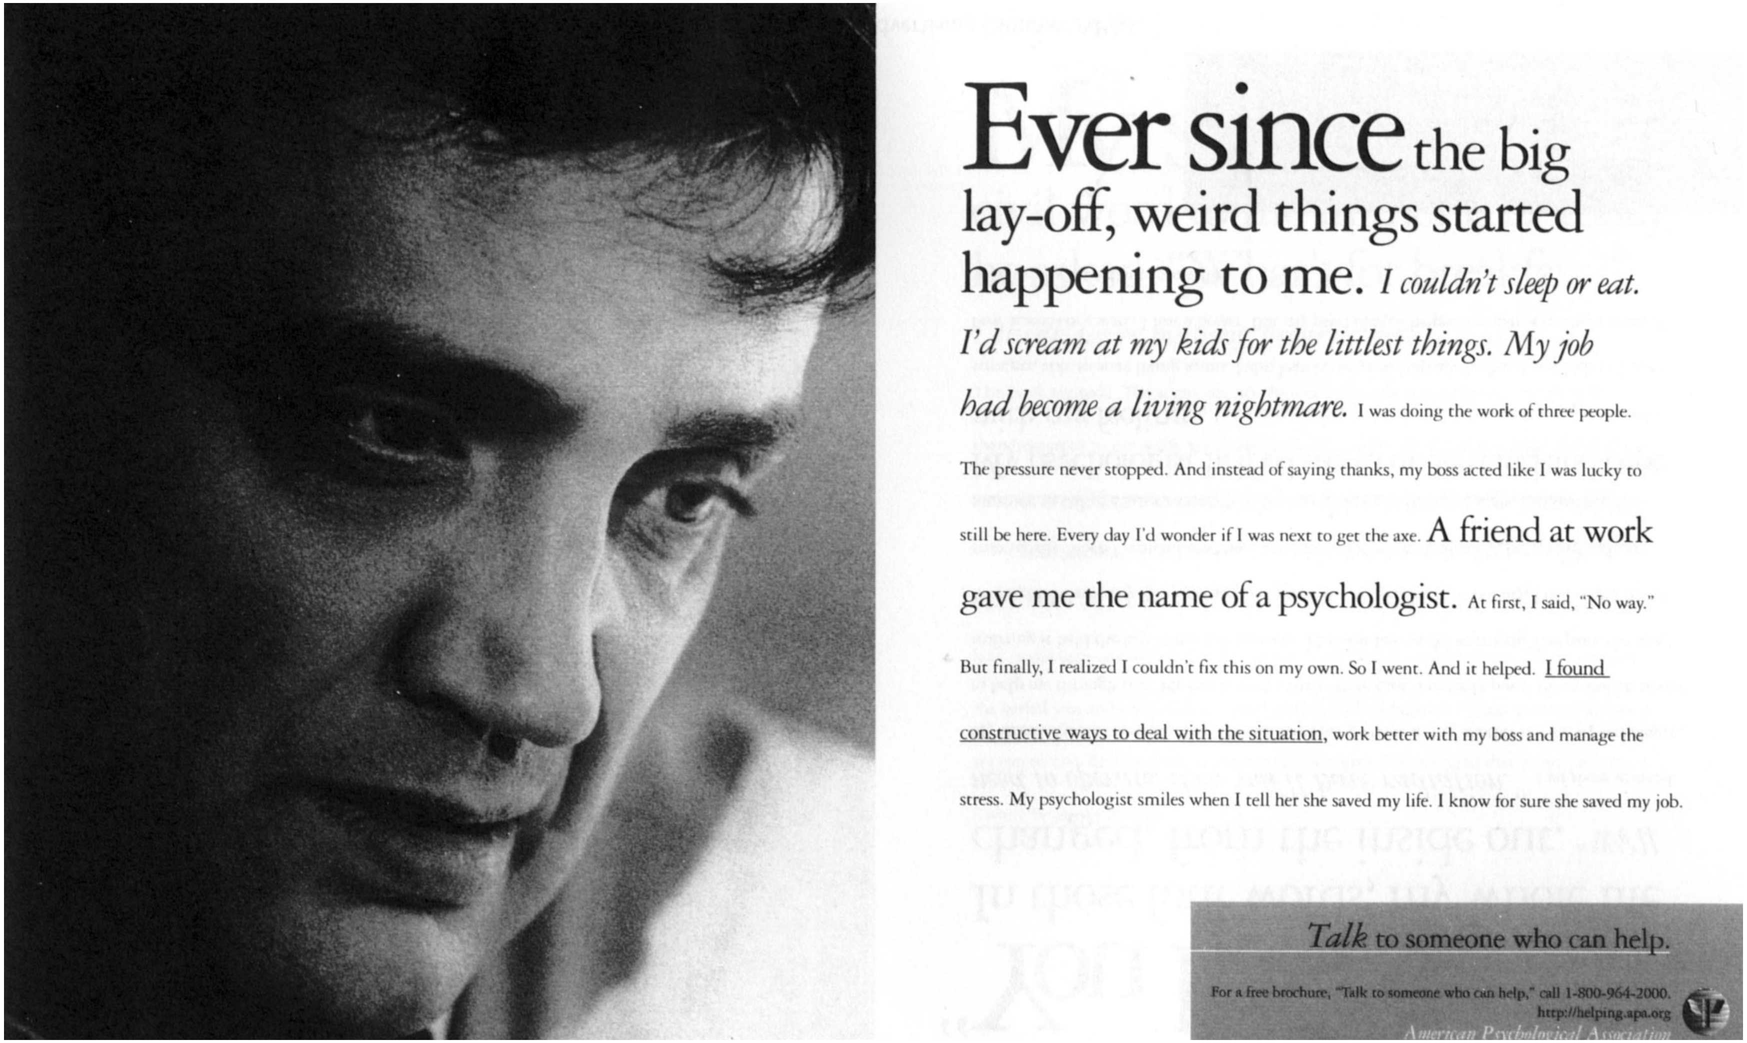
While in the past, the mass media helped create a false image of mental health providers, in the 1990s, many media personalities are helping to decrease the stigma around mental health issues through their own public acknowledgments of mental health problems. In 1987, Patty Duke revealed her battle with manic depression in an autobiography and in numerous public appearances on behalf of mental health causes. Newsman Mike Wallace has talked openly about his battle with depression as has columnist Art Buchwald.

Another promising media direction for the discussion of mental health issues was the early television talk shows. The format, pioneered by Phil Donahue in 1967, began as a serious and substantive place to discuss social issues that before were not discussed anywhere else. At their inception, the talk/interview format shows were a breath of fresh air and a new opportunity to discuss issues that affected everyone but that few people talked about, such as domestic violence, family relationships, race relations, and sexuality. Mental health professionals including psychologists were often invited to be part of these shows to comment and add a psychological perspective and knowledge to the discussion. Many hailed these shows as a way to "give psychology away" and help people who might not otherwise seek help.

Phil Donahue's show met with great success and popularity, and not surprisingly was copied. By the early 1990s there were nearly a dozen talk/interview format shows on the airways in America, each trying to outdo the other for ratings by being that much more provocative, outrageous, and obnoxious.

With few exceptions, TV talk shows became little more than organized, electronic bar-room brawls. During the final 60 seconds of the show, the mental health professional was asked to appear on air and solve the guest's problem, be it marriage infidelity (my mother slept with my husband is not an atypical show topic), eating disorders, body image disorders, gambling addictions, or a host of other serious and intensely personal life problems.

Heaton and Wilson (1995) have studied the TV talk show phenomenon and have written about it in their book *Tuning in trouble: Talk TV's destructive impact on mental health*. They write, "TV talk shows make a mockery of the mental health profession by obscuring the fact that change and recovery are most often a long and painful process. Innocent viewers, moreover, succumb to a "copycat syndrome" being persuaded that they too not only have the same problem, but can solve it with similar quick-fix, sound-bite therapy. Television talk shows entertain their enormous viewing audience with a steady stream of wounded guests, self-serving gurus, and manipulative hosts who offer quick



Ever since the big lay-off, weird things started happening to me. *I couldn't sleep or eat. I'd scream at my kids for the littlest things. My job had become a living nightmare.* I was doing the work of three people. The pressure never stopped. And instead of saying thanks, my boss acted like I was lucky to still be here. Every day I'd wonder if I was next to get the axe. A friend at work gave me the name of a psychologist. At first, I said, "No way." But finally, I realized I couldn't fix this on my own. So I went. And it helped. I found constructive ways to deal with the situation, work better with my boss and manage the stress. My psychologist smiles when I tell her she saved my life. I know for sure she saved my job.

"You have breast cancer."

In those four words, my whole life changed, from the inside out. *"We'll need to operate, then you'll have radiation."* I sat there stunned. My doctor's words flew past me. He said something about seeing another doctor, a psychologist, to help me through this. He handed me a little white card. I numbly put it in my wallet, never realizing it held the key to my full recovery. The next few weeks were hell. The pain, the fear, the anger. I was lucky. They got all the cancer. But to get better physically, I had to get better emotionally. Then I remembered the card. I pulled it out and called. What a relief to have someone to talk with, someone who is trained to do more than just listen sympathetically.

My psychologist helped me to understand and cope with my feelings. I was surprised to find how much better that made me feel—stronger, able to start living again. I also learned ways to help my husband and kids talk about how scared they were. I lost a breast. But my psychologist helped me gain a stronger sense of what's really important in my life.

My son hasn't said a civil word to me in months. Today he asked, "What's for breakfast?"

I think we're making progress here. It started when he was 15. The punk attitude. The smart mouth. At first I thought it was typical teenage stuff. But then he started to get really aggressive with me and defiant of any discipline. Every day was a battle. All I wanted was to be his father again, not the enemy. But I didn't know how. Then one day, a friend at work gave me the name of a psychologist my son and I could talk to. It's really helping. We're learning how to discuss our differences without always making it a confrontation. We've stopped the verbal jabs and stabs. Life is slowly getting back in balance. I know we won't always see eye-to-eye. And he needs to become his own man. I'm just glad that in the process, I won't be losing my son.

and easy solutions to complex problems. Can we afford to dismiss this drive-by psychology of Donahue, Geraldo, and Ricki Lake as just harmless entertainment?"

In late 1994, as the talk shows' battle for viewers came to fever pitch, the Public Affairs Office of the APA began recommending that psychologists should not appear on the daytime talk shows. The APA stated in a media alert announcing the decision, "No good purpose is served for the viewing audience nor for the profession when a psychologist is associated with a 27 minute screaming match and viewers are offered unrealistic, quick fix approaches to serious life issues."

By the early summer of 1996, the Talk TV phenomenon seemed to be wearing itself out and being replaced by new "old style" programing such as the Rosie O'Donnell show. However, the harm perpetrated on the public's understanding of and expectations of mental health providers (and respect for them) by these trash talk shows is yet to be known.

2.38.5 HOW SHOULD THE PROFESSION RESPOND?

Comical and inaccurate portrayals of mental health providers has created a stereotype image of the profession and has likely added to the stigma around mental health services. These issues challenge the profession to act to provide the public with more accurate information and a more accurate, more professional, more human image of its ranks. "It's critical that psychology communicate its value to many publics; consumers, the media, and policy-makers," says Dorothy Cantor, a past president of APA, "if psychology doesn't communicate about psychology, who will?" she asks.

2.38.5.1 Public Education Campaign

The public image of psychology has been the concern of "lone voices" in the profession for decades. Research studies of consumer information and attitudes have pointed toward the profession's need to better define and market itself to the public (Benjamin, 1986; Schindler et al., 1987; Webb & Speer, 1986).

In 1995, the APA Council of Representatives directed that the association undertake a national public education campaign designed to communicate the value of psychological services. The campaign was unveiled in February 1996 and is expected to be a long-term effort involving not only the national association but state psychological associations, APA divisions, and individual psychologists.

The campaign consists of advertising, news media relations, consumer information, and grass roots activities. The advertising (TV, radio, and print), the campaign's most visual product, carries the tag line "Psychology: Talk to Someone who Can Help" and features vignettes which attach psychological services to issues that Americans worry about, such as serious illness, raising children, and coping with job stress.

The overall goal of the campaign is to close the information gap that APA's research uncovered. In a changing health care marketplace, consumers act to protect their access to those services they understand, are comfortable with, and value. The campaign is designed to call the public's attention to psychology by linking its services to problems people worry about and then to educate the public about what psychologists do, how psychotherapy works, as well as the unique training and skills of psychologists (see Figures 2–4).

2.38.5.2 Psychology's Role in Reporting News Events

Gaining expertise in working with the news media is another important way in which psychology can reclaim its image and its image-making. The news media often call upon psychologists to help interpret or to comment on daily events. As major events unfold, the APA Public Affairs Office gets calls from print and electronic reporters looking for people to go on the air or on the record to help explain events. Examples of such events include the bombings, arrests, aircraft disasters, the controversy of recovered memories, post-traumatic stress disorder in earthquake survivors, and others. Tomorrow's news may be another opportunity for psychology to help redefine its image and display its knowledge of human behavior. However, in order to take advantage of this opportunity, individual psychologists must be prepared for the newsmaker role. The best way to get this preparation is to participate in media training programs (offered at APA's convention every year) and to practice those skills.

Without the resources to produce a new hit movie in which the hero is a competent, professional, sound, and humanistic psychologist, there are other ways in which individual psychologists can help redefine psychology's public image, for example, participation in grass roots public education activities and availability to the news media.

2.39.1 INTRODUCTION

Clinical psychology's very roots were planted firmly in its science base, yet also in its promise as a profession responsive to a wide range of human needs. Its essential focus was initially, and remains, on psychological and behavioral aspects of human functioning. Although its earliest foundations lay in general psychology emanating from Wilhelm Wundt's University of Leipzig laboratories in the 1870s, several traditions within psychological thinking are credited as contributing significantly to the development of clinical psychology as it is known today, and, presumably, to directions it will take in the future.

Korchin (1976), writing about major influences on clinical psychology, supported Watson's (1953) earlier identification of two traditions, other than the early European experimental influence, which have had marked impact: psychometrics and dynamic thinking. Rotter (1963), while noting the contributions of experimental and theoretical psychology to clinical psychology, pointed out the significance of clinical psychologists' gradual move from working predominantly in the 1900s–1940s with children and with assessment activities (in particular, intelligence testing) to functioning more as therapists and case managers since the 1950s. Arguably, a time of clinical psychology's greatest consolidation occurred during and just after World War II, when clinical psychologists joined other health care providers in responding to the many psychological needs of America's service men and women. Indeed, several psychologists considering the history of clinical psychology (e.g., Korchin, 1976; Shakow, 1969) relate the evolution of three major professional activities carried out by clinical psychologists—diagnosis, psychotherapy, and research—to World War II's special psychological needs. Korchin referred to these three activities as the "holy trinity of postwar clinical psychology" (1976, p. 45).

Later, fueled by political and social forces of the 1960s, the community mental health movement underscored psychology's importance to public health needs. By that time, clinical psychology was well established as one of the nation's major mental health professions. Just as the Veterans Administration (VA) had been singularly instrumental in advancing the education and training of psychologists to meet service needs following World War II (continuing its support to the present), the National Institute for Mental Health (NIMH) provided major support for the education and training of mental health professionals, including clinical psychologists in the 1960s, 1970s, and 1980s (with decreasing support in the 1980s and 1990s). Accordingly, clinical psychology has been responding to major public needs since the 1940s and, no doubt, will continue its commitment to national needs and priorities in the future.

Parallel developments in education and training also reflected clinical psychology's science and professional bases as well as its responsiveness to public needs. The Boulder Conference, led by American psychologists representing the American Psychological Association, the VA, and the NIMH, was held in 1949 for the purpose of developing standards for educating and training clinical psychologists (Raimy, 1950). One of the most enduring outcomes of the conference was the establishment of the scientist-practitioner training model, a model reaffirmed in several subsequent conferences (Korchin, 1976). In 1973, the Vail Conference addressed a lingering and also growing concern about how psychology could best educate and train clinicians to be responsive to changing and increasing demands for psychological services in both public and private sectors. A central question was how to assure clinical as well as research expertise, and conference deliberations on this matter led to the recognition of a new training model, one that emphasized professional training (Korchin). This recognition did not eliminate the scientist-practitioner model, which, in fact, continues to be observed by many graduate programs; rather, it broadened the ways in which graduate programs in clinical psychology would be designed and implemented.

Since the 1960s, as indicated previously, clinical psychology, both as a science and as a profession, has been recognized as a national player in public health, especially with regard to mental health. The NIMH, for example, has identified four disciplines as essential to addressing national mental health needs: clinical psychology; psychiatry; nursing; and social work. These four disciplines have been included in NIMH's applied and training programs, and as noted above, NIMH-supported clinical training programs provided major resources for several decades to assure an available pool of mental health service providers. Clinical training funding, divided among these four mental health professionals, was at the highest level of $93 million in FY 1967; regrettably, however, that level dropped to 10.9 million in FY 92 and to 2.9 million in FY 1993 (Callan, 1993).

Clearly, national leadership on mental health needs and services has been influenced considerably by NIMH-sponsored programs and directions. In the late 1980s, for example, NIMH in collaboration with others, including professional and advocacy groups as well as educators and trainers, identified four populations whose urgent mental health needs merited special attention: (i) seriously emotionally disturbed children; (ii) the seriously mentally ill; (iii) ethnic minorities; and (iv) the elderly. Clinical psychology was a central player in the series of conferences held between 1988 and 1992 on the education and training of health care providers for these particularly needy groups.

The mental health challenges of these groups, along with numerous other public problems, constitute a broad array of national needs to which clinical psychology has relevance. Arguably, they are apparent in all major human and social systems: in government, education, health, law and justice, transportation, environmental and community safety, communication, and in the worlds of work, art, and play. Individuals, families, and communities face myriad challenges in everyday living, ranging from meeting basic needs for food and shelter to higher order ones related more to quality of life. When special problems such as those of the underserved, under-represented, or the otherwise needy are also considered, the complexity and urgency are almost overwhelming. Identifying and addressing priorities among them, especially in the context of an increasingly complex and diverse society, are daunting tasks. Moreover, effectively responding to them on a national scale will certainly require the knowledge and skills as well as the caring of many. Not only must clinical psychology play a leadership role in this response, it must become an active, ongoing partner with other psychologists, other professions, and the public.

2.39.2 SELECTED NATIONAL PRIORITIES

In order to provide such leadership and build such partnerships, it is imperative that clinical psychologists become well informed on national needs. This chapter, building on the history of clinical psychology, focuses on selected national priorities, first identifying several key need categories and then elucidating the urgency associated with each and the implications for clinical psychology. Four need categories are presented: (i) health care (including mental health); (ii) education; (iii) work and economics; and (iv) families and communities: relationships, systems, and communication.

Although these categories take into account special populations, such as the four identified by NIMH, they provide a broader context, one identifying the larger human and societal needs that constitute national priorities for the USA as the twenty-first century nears. Reflecting overarching challenges, they highlight the broad scope as well as the complexity of national issues with which clinical psychology can engage in the next few decades and thereby make a real and dramatic difference for humankind. As clinical psychologists become both better informed and actively involved in addressing national priorities, the relevance and promise of clinical psychology as a science and as a practice will achieve heightened visibility and meaning.

2.39.2.1 Health Care

Rapidly escalating health costs since the 1970s as well as diminishing access to health care have mandated health care reform. According to Resnick and DeLeon (1995), cost estimates for health care in 1993 were around \$880 billion; moreover, access to health care is becoming nonexistent for many Americans with almost 40 million Americans lacking health care coverage and an estimated two million losing health care coverage each month. Mental health costs have been spiraling as well. Annual costs of depression exceed \$43 billion (Greenberg, Steglier, Finkelstein, & Berndt, 1993), while the annual overall expenses associated with mental health and substance abuse is \$273 billion (Rice, Kelman, Miller, & Dunmeyer, 1990). Inpatient substance abuse services grew 30% between 1986 and 1988, and adolescent inpatient treatment grew 65% ([see Frank & Salknero, 1990], as reported in Slosar & Lettieri, 1996).

Unquestionably, health care reform is a national priority, and only those disciplines actively engaged in the reform process will influence the directions it takes, an involvement that is critical in the face of such developments as expanding managed care. Indeed, in order to have a viable future, clinical psychology must exercise a leadership position in national health care planning and service delivery. Its leadership must be positioned from the broadest possible base, focusing on health care and not limited to mental health care, with which it has been associated in the past to a large extent. Although psychotherapy remains an established and effective modality (see below), it cannot stand as the *sine qua non* of clinical psychology. The developing trend since the 1980s in which clinical psychologists have been increasingly assuming roles more associated with general health care must persist.

Behavioral health research and service delivery constitute an area of general health care to which clinical psychology has natural relevance. In fact, clinical psychologists as well as health psychologists have become increasingly involved in professional activities related to behavioral health since the late 1970s. Among the many compelling behavioral health problems existing in the USA today requiring both further research and the development of more effective prevention and treatment strategies, one of the most pressing is drug abuse. Indeed, in its different forms and combinations, the abuse of drugs has reached such impressive levels as to have been identified as one of the nation's highest health and social priorities.

Alcohol dependence and abuse are among the most prevalent national disorders within America, for example, as reported in the *Diagnostic and statistical manual of mental disorders* (*DSM-IV*) (American Psychiatric Association [APA], 1994), and at a terrifically high price: in 1988, for example, costing $>$\$58 billion (National Institute on Drug Abuse, 1990). Of the 73% among the population reporting use of alcohol, $>$19 million are problem drinkers according to Winick (1992). Also according to Winick, another group, consisting of the approximately 36% of the population who are cigarette smokers, a figure representing a slight reduction from several years ago, actually constitute an especially alarming problem, given the upsurge of smoking among young people (Winick, 1992). A parallel problem involves the increasing number of adolescents and young adults who are using marijuana. Approximately one-third of the population reports the use of marijuana one or more times, making it among the most widely used drugs (APA, 1994). It has been described by Johnson and Muffler (1992) as the most frequently used illicit drug in the nation among those using drugs recreationally or intermittently and also among the most common secondary drugs used by abusers of other drugs, along with alcohol and cigarettes.

The same authors indicate that one of the more recent and threatening illicit drug developments has been the rapid invasion and increased usage of crack cocaine in the USA since 1985. Admissions for cocaine users rose from approximately 2000 in 1983 to >11 000 in 1989 (most for crack cocaine abuse rather than cocaine snorters), and treatment modalities and programs are insufficient to address the increased number of abusers. These authors caution that "much is unclear about how long the crack era will last and how long its effects will persist" and underscore the "crying need for a new treatment approach that is even modestly effective" (p. 127).

Referring to the "terrible tragedies" that arise out of drug abuse, Lowinger (1992) notes that it is among the nation's poorer citizens and also the infants of drug-addicted women that the greatest toll is exacted. His admonition is:

> Society has a stake at least in reducing, even if unable to eliminate completely, such tragedies. If it is to do so effectively, the true issues that must be dealt with are unemployment, poverty, racism, sexism, and feelings of powerlessness and alienation in our society. Every American has the right to hope for a future that can provide healthy sources of self-esteem, pleasure and affiliation. (p. 141)

Preventing and ameliorating costly and painful physical as well as psychological problems associated with such abusive behaviors are clearly critical health care goals. Psychologists are challenged to become professionally involved with interventions that effectively interrupt the addictive cycle, including behavioral as well as other approaches. Clinical psychologists may serve not only as consultants but also as program designers and managers for a variety of health programs and interventions, and, of course, they may continue to make critical contributions through their research expertise, as suggested by Barlow, Hayes, and Nelson (1984). As Nirenburg (1983) indicates, clinical psychologists work effectively in the treatment and management of addictive behaviors such as alcohol abuse, obesity, cigarette smoking, and drug abuse with a variety of treatment techniques including social skills training, problem-solving skills, vocational skills, chemical treatment, aversive conditioning, and relaxation.

Clinical psychologists provide valuable services for other health problems as well, and it is likely that such contributions will be in even greater demand in the future. They provide neuropsychological evaluations and treatment planning for brain-injured patients, for example, clinical services that can be expected to become even more sophisticated and accessible in parallel with anticipated technological advances. Clinical psychologists also contribute creatively by developing and managing prevention programs (Lorion, 1991), one of the most promising clinical efforts, from both cost-saving and disease prevention perspectives.

Even as clinical psychologists are assuming a broader role in general health care, however, they must continue to be skilled psychotherapists. Psychotherapy remains a viable and effective clinical tool, demonstrably a treatment of choice for a wide range of health problems. Even though further research will be helpful in demonstrating its value as a clinical treatment to a broader audience of health service providers and the general public, psychotherapy has already been shown to be an effective intervention for both physical and psychological problems. Reviews of recent research elucidate psychotherapy's efficacious and cost-saving contributions in alleviating or contributing to the cure of both physical and mental illnesses, a particularly critical finding in these times of managed care practices that delimit intensive and long-term psychotherapy. Lazar (1997), for example, identifies several mental health populations who benefit markedly from extended dynamic psychotherapy: patients with anxiety disorders, especially children; depressives, especially adolescents and also those with interpersonal and self-esteem symptoms; and post-traumatic stress disorder, borderline personality disorder, and multiple personality disorder patients as well as schizophrenics. Further, in describing positive outcomes from intensive psychotherapy with patients having certain physical illnesses, Lazar notes such dramatic results as increased survival rates for metastatic breast cancer patients in psychotherapy and points out as well the value of extended group psychotherapy in such health promotion programs as diet and exercise regimens and also refers to the greater stability of diabetic patients in three to four times a week psychotherapy.

It is ironic that a country with such a high degree of expertise in health care—supported by comprehensive research activities resulting in elucidating findings such as those on efficacious treatment noted above—has so many people to whom health care is either minimally provided or absent altogether. In the face of such inequity and, moreover, in the best interests of the general public, clinical psychology is challenged to bring to bear its knowledge and skills, as well as its essential regard for the human condition, as an energetic player in health care delivery. Not only must it address the wide range of health issues for which it has both relevance and promise, clinical psychology must assume energetic and assertive leadership for national health policy development and administration. Indeed, from both research and practice perspectives, clinical psychology has much to offer. Its expertise is key to the success of future health care delivery in this country.

2.39.2.2 Education

The USA's commitment to education is interwoven in its history as a nation. Both before and after the Revolution, leaders such as Thomas Jefferson and Benjamin Franklin were advocates for educating the masses, given what they saw as the "intimate relationship between educational opportunity and social, political, and economic education" (Gutek, 1991, p. 28). Jefferson strove diligently for many years to implement public education at all levels, from the lower grades through higher education; however, he achieved success only in the establishment of the University of Virginia. Although early resistances such as he encountered slowed national efforts to educate the masses, gradually throughout the nineteenth century progress was realized first with the establishment of common schools and then high schools. Cremen (1988), tracing America's commitment to education as reflected in the views of Thomas Jefferson, Horace Mann, and John Dewey, and also through conservative as well as progressive national administrations, pointed to the influential role of education in America:

> The notion of education as holding the key to the achievement of the nation's most fundamental political aspirations—of racial integration or social quality or economic productivity—remained constant, indeed no longer a characteristic progressive idea but increasingly a characteristic America idea, held with the same depth of commitment that had attached to religious belief during an earlier era in American history. As American education went, so would go the American people and the American nation. (p. 155)

Arguments supporting psychology's applications to education can be traced back to Herbart and, from a specifically more American perspective, to William James' *Principles of psychology* (1890) (James, 1952) and his subsequent writings on psychology and education. Indeed, among the many theoretical influences impacting American education in the late nineteenth and twentieth centuries, theories of psychology were among the most influential.

Even with continuing support for public as well as private education up to the present time, education has suffered strong criticism in the last couple of decades, in sharp contrast with the positive regard it enjoyed during the years of the education heyday that followed World War II. In the 1950s, for example, the promise of a high school education for all Americans and the expectation of an opportunity for higher education or training were fostered by the implementation of a number of federal programs, including the GI Bill. After the 1960s, however, not only have both dimmed considerably, but, as reflected in *Education: A nation at risk* (US National Commission on Excellence in Education, 1983), concerns about the overall lack of quality in America's educational programs have increased. As a result, the general public has joined educators and policymakers in demanding education reform. Holtzman (1992) writes that "major reform in public education, perhaps even radical changes that would scarcely have been voiced a generation ago, will be the driving force to ameliorate" many of the social problems such as "community renewal, family preservation, child development, and education" (p. xiv).

From a national perspective, specific priority areas of education reform have been identified and supported in important pieces of legislation, for example, those outlined in *Goals 200: The Educate America Act* (PL 103-227), passed in March, 1994, and *The Improving America's Schools Act of 1994* (IASA, PL 103-382). One section of IASA focuses on safe and drug-free schools and communities, acknowledging and responding to the nation's serious drug abuse and violence problems. Given the prevalence of these problems, especially among youth, and their invasion into the schools, clinical psychologists have a particular responsibility, and are in a special position, to address them. Findings from their research have already been invaluable to policymakers, for example, as in legislative decision-making around such matters as appropriate television programming for children (Wilcox & Kunkel, in press).

Another development which has become a major influencing factor in education reform is the view that early education programs as well as K-12 schools must address emotional and adjustment needs of students as well as content requirements. A related movement has advocated the provision of school-based services, including health care services. These developments are particularly inviting to clinical psychologists, whose research and applied expertise are so relevant to both: (i) the emotional development and adjustment of children and adolescents; and (ii) cognitive and learning strategies. Although this relevance is well established, it has been the case that for a good part of this century, psychologists, apart from school and educational psychologists, have not been consistently involved with schools. Many clinical psychologists, for example, may have worked with patients or clients on school-related problems (e.g., through professional activities with parents and students, including assessment and interventions), but not have spent many professional hours actually in school settings. As a result, they may not have been as informed on national education developments and needs in the past as will be required with anticipated greater state control, as, for example, in the context of school-based services.

A related development in education, the emphasis on early childhood education as well as parent–child development programs, has been of particular interest to psychologists for some years (e.g., Holtzman, 1992; Johnson, 1988; Johnson & Walker, 1987; Walker, Rodriguez, Johnson, & Cortez, 1995, Zigler, 1989; Zigler & Lag, 1991). A good deal of effort has been expended in implementing these programs in high-poverty areas, and both educators and psychologists have been encouraged by initial as well as subsequent reports indicating positive outcomes with respect to both cognitive and emotional development, for example, managing behavioral problems. More recent information, however, suggests that these promising outcomes are not maintained over time unless other kinds of interventions are included as well (D. L. Johnson, personal communication, July, 1996; Johnson & Blumenthal, in press). Specifically, positive gains seem more likely to persist when mothers of the children enrolled in the early education programs are supported through corollary education and training programs. On completion of the two-year Avance program in San Antonio, for example, more mothers went to work, and it is anticipated that this outcome will lead to better economic futures for the families which will, in turn, support a longer-term maintenance of the positive behavioral and academic gains realized by the children in the program (Walker et al., 1995). Results such as these suggest exciting possibilities for psychologists and educators interested in integrating and implementing early childhood education and parent–child development programs. Clinical psychology has much to offer in such efforts to advance early childhood education and development opportunities, and it can be a major player in assuring that these gains, which otherwise might remain only temporary, are maintained.

Other recent and mounting concerns, also related to the emotional needs of K-12 students, have been identified by Claire Ellen Weinstein, then President of the American Psychological Association's Division 15 (Educational Psychology), concerns supported by Gutek (1991) about persistent issues and challenges facing American education. While acknowledging the importance of *Goals 2000*, Weinstein extends the focus she believes educators and psychologists must pursue by identifying three key issues related to the current emphasis on the personal and social development of students: transitions, literacy, and self-system variables (C. E. Weinstein, personal communication, July, 1996). Enthusiastic in the hope that psychologists will more fully address these critical issues in the future, Weinstein stresses the necessity for collaboration between clinical psychologists and both educational and school psychologists. Such urging seems particularly valid, given: (i) the striking demographic and cultural changes taking place in our communities which are impacting our schools; and (ii) the resulting need for integrated responses and services.

Self-system variables are considered here briefly in respect of space limitations; they are selected from the three noted by Weinstein to emphasize the centrality of personal and social adjustment issues to the learning process. Moreover, not only is a focus on self-system variables particularly congruent with clinical psychology's domain, it is also especially relevant to understanding and addressing social and cultural challenges growing out of the increasing ethnic and cultural diversity in both urban and rural populations. Educators are experiencing great need for psychological understanding as they attempt to respond in school settings to the rapidly increasing, nationwide diversity. As children from diverse backgrounds and cultures enter local schools, speaking different languages and reflecting vastly different family as well as cultural values—for example, regarding such basic matters as parenting, religion, gender roles—challenges to educators are impressive. Administrators and teachers must have support in understanding, appreciating, and working in the context of self-system variables as they are reflected by students as well as their families and communities. Equally important, educators must have opportunities to consider how their own values relate to dramatically changing systems.

Student and family beliefs, expectations, and goals, for example, not only determine significantly how students perceive their school environments but also how well they will perform. How such views fit within specific community as well as administrative and teacher cultures can be a major determining factor regarding if and how students become and remain engaged in learning. As clinical psychologists work with families and children experiencing school-related problems, they are likely to find their understanding and interventions informed by determining the nature and fit of self-system variables that are obtained in a specific situation. From a school-based perspective, as psychologists gain greater appreciation for these kinds of interactions, they are likely to have opportunities for supporting an effective rapprochement among students, their families, and their teachers. An integrated and interactive approach on the parts of educators and psychologists seems congruent with Holtzman's view that psychologists can be "in the forefront of bringing about the necessary changes and scientific advancement" for education reform to succeed (Holtzman, 1992, p. xiv).

2.39.2.3 Work World and Economics

Radical changes in the world of work are impacting every family and community unit in our society in one way or another. Not only has the composition of professionals and workers changed significantly with respect to diversity (e.g., gender and ethnicity), the nature of work itself has changed remarkably. Technological advances alone, for example, have made for sea changes in the work setting. Computers and other digital products are used by 50 million workers every day (Cascio, 1995). A more gradual but nonetheless dramatic change in workforce composition is the increasing number of women working outside the home. Not only are more women working, more women are in the professional arena and more are working full-time. The increase of mothers in the workforce increased from 57% in 1980 to 68% in 1994 (Hartmann, Spalter-Roth, & Chu, 1996).

These workforce shifts contribute to major changes not only in the work place but also among families and communities. Included in the national-scale demands created by such changes are child and family care needs; health and safety issues in the work place, both physical and psychological; and job satisfaction and fulfillment, free of excessive stress. Changing standards and expectations on acceptable working conditions and settings as well as expected work place behaviors and relationships are leading to new and interesting developments. Harassment issues, for example, were almost unheard in the 1980s; yet, they are so much in the forefront today that alert human resources offices are conversant in the legal as well as everyday practical implications of such matters. Quite different from expectations a few decades ago, most workers today seek benefits for themselves and their families, and they expect protection from violence and injury in the work setting. Stress in the work place is another pervasive work problem, and clearly it is one to which clinical psychologists can bring considerable relevant research and applied expertise, as are the other critical work-related matters just noted.

Still another development, a key economic matter which has significant psychological ramifications, involves the changing nature and availability of jobs and raises questions about job security, thus, about family security. The fairly recent transition from an industrial society to a technologically driven one has been revolutionary with both positive and negative outcomes. Workers at all levels without computer skills are likely to find themselves unable to gain employment in many future work situations. On the one hand, business can be conducted more quickly and with greater ease as a result of technological advances, and more complex tasks can be completed and integrated than can be accomplished manually. On the other hand, companies and agencies, able to replace people with computers and other technological advances including mechanical operations, are downsizing, one result of which is that individuals who had expected lifetime job security are finding themselves among the unemployed. Tying downsizing to several other factors as well, including efforts to improve productivity, location moves, mergers, and new ways of organizing work, Cascio (1995) notes that seven million layoffs have occurred since 1987, and asserts that downward mobility is now the rule, not the exception.

What about the already unemployed? As expected welfare system changes are initiated in the next few years, communities will be faced with how the currently unemployed, including single mothers, will find employment providing them with a necessary income. Among the disadvantaged living in the USA, the largest group comprises single-mother families. They constitute 60% of all poor families with children, and those living in these families constitute 22% of all poor people (Hartman et al., 1996); or, put another way, in 1994: "44 percent of single-mother families were poor, compared with 8 percent of married-couple families with children and 12 percent of people over age 65" (p. 24). Clinical psychologists, along with others, such as the Institute for Women's Policy Research, surely are challenged to study factors contributing to this regrettable status and develop strategies for assuring upward change.

Based on studies investigating job availability in low-income areas, questions have been raised regarding the assumption that stopping state support will force welfare recipients to "join the labor market and support their children with honest jobs" (Newman, 1996, p. 20). Results indicate that the going may be tough, especially in geographical and target areas that will start from a low point—as in one inner-city neighborhood study, for example, where there was 18% unemployment with 40% below the poverty line and where new jobs were in short supply. One specific finding noted that "the ratio of jobseekers to successful hires in the fast-food restaurants studied in Harlem is approximately 14 to 1; moreover, among those rejected, 73% had not found work of any kind a year later" (p. 21). Those groups most frequently rejected were: younger applicants, especially 18 years and under; African-Americans, as compared with Latinos and others; residents of the neighborhoods, as compared with applicants commuting to work from other neighborhoods (a complicating factor for young mothers who need to work near their children); those without "connections," that is, those outside of friend and family networks; native-born applicants, as compared with legal immigrants; and those without prior work experience.

Such findings underscore the importance of developing and implementing programs to address job training and also those to create new jobs. The former need relates, interestingly enough, to reports on parent–child development programs (e.g., Walker et al., 1995). Although oftentimes in the past, such efforts have been viewed as largely the domain of private industry and business, or of government, it is clear that the development of new approaches informed by psychological understanding is a major economic priority for this country. Among some current views of welfare mothers are depictions of them as "welfare queens," as pathological, and as lazy, whereas others look to socio-cultural problems, including increasing numbers of teenage pregnancies, high divorce rate, lack of education and job training, as the major contributors (Newman, 1996). The resolution of this complex cluster of social and economic problems certainly could be aided by research as well as other expertise from clinical psychology. Moreover, in the context of broad collaboration with other scientists and professionals working closely with local communities as well as state and national policymakers, clinical psychologists could contribute significantly to new and better integrated approaches.

Such national work-related problems have vast implications for clinical psychologists, as they do for the general public. Clearly, considering such factors as emotional satisfaction, stress management, and the promotion of mastery and productivity, there are a number of national priorities which clinical psychology can appropriately address. There exist a number of opportunities involving collaboration with industrial and organizational psychologists, as supported by Cascio (1995): there is "an exciting agenda with large potential payoffs for individuals, organizations, and society as psychology moves into the 21st century" (1995, p. 938).

2.39.2.4 Families and Communities: Relationships, Systems, and Communication

That a central theme of both 1996 national party conventions, Republicans and Democrats, reflected the strong concern of Americans about the health, wealth, welfare, and happiness of the American nation's families and communities appears to be no accident or mere coincidence. Indeed, individuals across the USA openly express a yearning for greater individual opportunity but in the context of healthy and meaningful relationships, particularly those associated with family and community. They seek safe and supportive environments, ones that allow them to pursue their personal, family, and community goals. Clinical psychology is in an especially advantageous position for studying not only the kinds of changes that would respond to this yearning but also interventions which might best facilitate such changes. Outcomes from such programs as the Avance project, for example, are yielding provocative and exciting possibilities for bringing about changes in our communities (Walker et al., 1995). Clinical psychologists are challenged to work, not only with educators and collaboratively with other psychologists from various specialty areas, but also with local communities as well as state and national groups, to develop programs that better support children and their families. They can also serve as advisors to state and national legislators who are struggling to gain relevant, valid information about individuals, families, and communities in their various social, educational, and economic systems that would enable them to make better decisions in all public arenas on behalf of their constituents. Clinical psychologists must continue to be at the ready to provide information and counsel on matters of national priority to families and children, responding with critical leadership as they have in the past on such issues as teenage pregnancies and the negative influence of television violence on youth (Wilcox & Kunkel, in press).

Among the many family and community issues viewed as national priorities by leaders and policymakers as well as the general public, there are three that seem to be among the most pressing: violence, increasing diversity across the nation, and the social and economic problems associated with situations of disadvantage, the latter including poverty and the related high incidence of drug abuse. Again, given space considerations, violence is considered here, as an exemplar of the three, because of the particularly urgent need for relief through effective interventions, and also because, as a matter of national crisis, it has compelling implications for the future work of clinical psychologists.

Arguably, violence is one of the single greatest problems facing the USA and the world today. Possibly the USA's most devastating social and human problem, it strikes and is felt in every context of life: families, schools at all levels (preschool through 12 and on into higher education), the workplace, and in communities. Indeed, because the cost of violent events and actions is so great and the damage so extensive, the prevention of injury is an identified priority for federal and state public health offices. The Center for Disease Control and Prevention in Atlanta, part of the United States Public Health Service, has as one of its major priorities the development of further understanding and strategies for addressing the prevention of intentional and unintentional injuries. Recent violent and highly visible events, such as the April 1995 Oklahoma City bombing of the Alfred P. Murrah Federal Building, the 1995 Simpson trial, the June 1996 Saudi Arabian bombing of the American Marines' housing, and the July 1996 TWA plane crash in New York, have received wide media coverage, drawing attention to the pervasiveness of violence, or suspected violence, in American life. The visibility of these events demonstrates dramatically the destruction and pain that individual dissidents, those who are deeply psychologically disturbed, alienated groups, and others can inflict on families and communities.

Studies on the incidence and patterns of domestic violence indicate that at least half of the injuries sustained by women are related to partner abuse, and in some age groups, more than half of all reported rapes are committed by partners. Women are much more likely to be abused than men. Even though women may have reported injuries multiple times to their physicians and in emergency rooms, the violent causes of their repeated injuries may not be discerned. Recent litigation in several states involved violence to women in the workplace, from sexual harassment to alleged murder.

Every day in America: three children die from child abuse; 15 children die from gunshots, 135 000 children bring guns to school; and 1.2 million latchkey children come home to a house where there is a gun. Recent analyses show that in addition to the high price in psychological anguish paid by individuals, families, and communities as a result of violent behaviors and acts, physical injuries suffered by the victims of violence are increasing in number. The numbers are so staggering that the American Medical Association construes epidemic violence as a leading cause of death. Prevention of injury is an identified priority for federal and state public health offices.

Clinical psychologists are poised advantageously to address violence issues. Not only can they conduct requisite research to better understand the etiology and course of violent behaviors and acts in different contexts, they are already leaders actively involved in the development and implementation of effective interventions (e.g., Cohen & Mannarino 1996). Using their understanding about human motivations and conditions that lead to violence, they are poised to develop strategies and interventions to ameliorate, relieve, and dissipate individual and community violence. Clinical psychologists have a particular responsibility to work in interdisciplinary programs focusing on the development and implementation as well as the evaluation of such strategies and interventions, including interdisciplinary training programs (e.g., see Gallmeier & Bonner, 1992).

2.39.3 SUMMARY

Hubert Humphrey, Vice President of the USA from 1965 to 1969, once said:

> The moral test of government is how it treats those who are in the dawn of life—the children; those who are in the twilight of life—the aged; and those who are in the shadows of life—the sick, the needy, and the handicapped. (quoted in Edge & Groves, 1994, p. 2)

The subtitle of a 1996 publication titled *Psychology and public policy* (Lorion, Iscoe, DeLeon, & VandenBos, 1996), places this quote in an appropriate context with respect to clinical psychology's responsible and effective response to national priorities: "Balancing Public Service and Professional Need." In the foreword to that publication, Fowler says that "psychologists do not operate in a social vacuum" (p.ix), and he goes on to assert that psychologists' "theories must recognize social realities, their methods must allow for differing attitudes and behaviors, and their treatment must respond to socially defined psychological and behavioral problems" (Fowler, 1996, p. ix).

These authors identify a reciprocity between the importance of policy to the profession and that of the profession to policy formulation. As described, this reciprocity makes explicit the imperative that psychologists engage in national policymaking as well as in professional activities directly addressing national needs. Clinical psychologists, of course, are challenged accordingly, if not especially, to engage in clinical research relevant to national priorities and in applied contributions responsive to the country's most pressing social and human problems.

This chapter's focus serves that charge by presenting and elucidating four broad areas reflecting current national priorities and, then, by noting clinical psychology's relevance to, and encouraging its engagement with, them. With an impressive history in this regard and great promise for addressing human need, welfare, and happiness, clinical psychology should do no less.

2.40.1 NEEDS OF OLDER ADULTS IN JAPANESE SOCIETY

By 1995, life expectancy in Japan reached 76.5 years for men and 82.98 years for women. Also by 1995, Japanese life expectancy had been the highest in the world for 10 consecutive years for men and 11 consecutive years for women. This trend will continue.

Japan joined the list of nations with great longevity in the 1970s. In the years before World War II, Japan was a developing country, lagging far behind Western countries in terms of life expectancy. In 1935–1936, life expectancies for Japanese men and women were 46.92 years and 49.63 years, respectively, while life expectancies for both men and women of other countries such as Holland and Sweden were over 60 years.

According to World Health Organization (WHO) statistics, a nation is categorized as having an aging society if the ratio of people aged 65 and older exceeds 7% of the entire population. Figure 1 (Japanese Ministry of Health and Welfare, 1994) shows changes in the ratio of people aged 65 and older in major countries between 1950 and 2025. In Japan, the ratio became 7% in 1970 and it took only 25 years for the figure to double, reaching 14% in 1995. Furthermore, it is evident that the aging of Japanese society is proceeding at a drastic speed when compared to an 85 year period for Sweden (7% in 1890 and 14% in 1975), a 70 year period for the USA (7% in 1945 and an estimated figure of 14% in 2015), a 50 year period for the UK (7% in 1930 and 14% in 1980), and a 45 year period for Germany (7% in 1930 and 14% in 1975).

It is also noteworthy that the population of those aged 65 and older in Japan will continue to increase at a rate that will not be observed in any other country, and will reach an estimated figure of 21.3%, the highest in the world, in 2010. An ultra-aging society is expected in Japan by 2020.

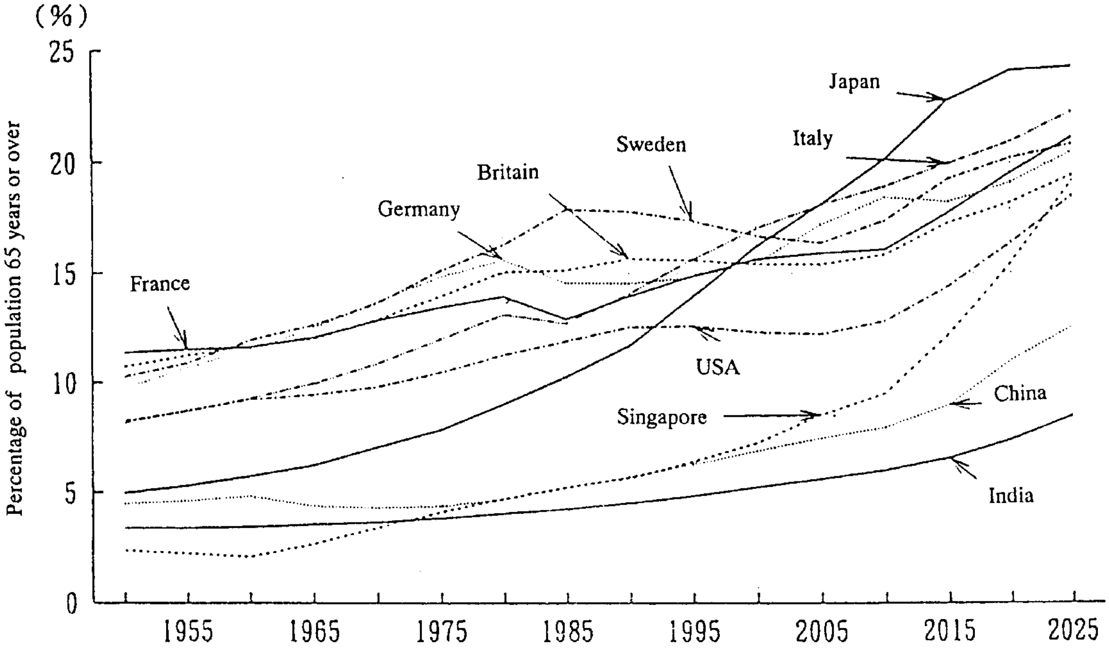

Figure 1 Changes in ratio of people 65 and over in Japan and other countries.

Now that Japan is facing an aging society, various issues concerning the aged are surfacing. One of the important issues is the change in family structure. The traditional Japanese family system (three generations in one household) started to break down after World War II, and "the nuclear family," which had long been common in Western countries, began to take over. The ratio of those aged 65 or older living with a child was 68% in 1975. The figure had dropped to 55.3% by 1994. This figure, however, is still high compared to such Western countries as the USA, the UK, and Sweden.

The ratio of those aged 60 and over who prefer to live with a child or grandchild is 53.6% in Japan, quite a high figure compared to that of Germany (15.4%), the USA (3.4%), and the UK (3.9%) (Japanese General Affairs Agency, 1992). Despite the fact there are more elderly in Japan who live with their family and who prefer to do so than in other countries, the ratio of those who felt lonely was over 50%, much higher than in the USA and the UK. This suggests that there is a wide gap between the expectations Japanese elderly people have of their family and the reality of their daily life. The same can be said about how they feel about work after retirement.

As to how Japanese elderly people feel about having a postretirement job, 35.9% replied that they would "work as long as they are healthy" and 22.7% replied that they would "work until they were about 70." These two figures together show that more than half the population of elderly people in Japan are willing to work (Japanese General Affairs Agency, 1995). In reality, however, the employment rate of those aged 65 years and older had dropped from 38.1% in 1962 to 24.3% in 1994.

The most common motivation for those who wanted to work was "the desire to make friends." The motivations given in other countries such as the USA and the UK were "earning money" or "enjoying work." This difference indicates that elderly people in Japan have little interaction with their community and reveals the fact that they are living with a feeling of loneliness.

Another difficult issue regarding the elderly in Japan in the 1990s is that of frail or demented elderly people. In 1990, there were approximately 1 million cases of senile dementia nationwide, and this figure is expected to climb to 1.5 million by the year 2000, and 2.47 million by 2015. The number of elderly people who are frail or bed-ridden was 810 000 in 1990 and it is estimated that this figure will triple to 2.29 million by 2025 (Japanese Ministry of Health and Welfare, 1992). At present, there are 15 caregivers (careworkers or family members) to one elderly person. By 2025, however, there will be only two caregivers for one elderly person, a very severe reduction.

According to a survey conducted by the Ministry of General Affairs in 1995, 41.5% of the elderly aged 65 and older wish to receive care at home, and 54.8% of those expect their family members to assume this task. But, since 1985, the number of people in the younger generation who consider looking after their aged parents an obligation has been decreasing drastically, and they tend to consider living with their parents and supporting their parents as separate matters (Japanese Ministry of Health and Welfare, 1996).

Despite the fact that this gap between the expectations of the elderly and the consciousness of the younger generation has started to become clear, in reality, one out of four people aged 65 and older who died had received care from their family members while bedridden for more than half a year. Female members of the family are more likely to assume the responsibility of taking care of elderly family members than men in the following order: the elderly person's wife (31.6%), the wife of the eldest son (27.6%), and the eldest daughter (15.5%). Only 5.0% of the elderly persons' husbands assume such responsibilities. It is reported that more than half of those who assumed these responsibilities had jobs and 20.6% of them had given up their work to take care of an elderly family member (Japanese Ministry of Health and Welfare, 1996).

The responsibility of caring for the elderly increases the fatigue and stress of the responsible family member. There have been reports in newspapers, albeit few, regarding elderly abuse and murder of old people. Abuse and murder of the elderly appear to be associated with their caregivers' added fatigue and stress.

2.40.1.1 Clinical Psychological Services Sought in Japan

Since the Japanese Association for Certification of Clinical Psychologists was established in 1989, the number of certified clinical psychologists has been increasing year by year. In 1997, more than 5000 clinical psychologists are working at various institutions or in private practice. The Association of Japanese Clinical Psychology has more than 7000 members, and the number of research papers presented at its annual congress has also been increasing. The Education and Training Committee of the Association of Japanese Clinical Psychology conducted a survey on the content of the clinical psychological services provided by its 2296 new members for a period of six years from 1986 to 1991 (Association of Japanese Clinical Psychology, 1993). Data were obtained by multiple choice responses. 53.6% of the clinical psychologists surveyed were full-time workers, their most common workplaces being hospitals (37.9%), followed by counseling centers in universities and schools (15.7%), and child guidance clinics (15.3%). Almost 70% worked at the aforementioned three workplaces. Other workplaces included welfare facilities for rehabilitation (6.3%), court (6.8%), private clinics (4.8%), research institutions (3.5%), mental health centers and health centers (3.3%), the Ministry of Justice (1.9%), and others (4.5%). 22.3% of the clinical psychologists surveyed were part-time workers.

The ratio of part-time workers working for hospitals was 24.2%, which was lower than that of full-time workers. However, the ratios of part-time workers working for child guidance clinics (29.0%), private clinics (12.4%), and mental health centers and health centers (11.8%) were higher than those of full-time workers.

Regarding the contents of the clinical psychologists' work, psychological therapy was the most common (70.6%), followed by psychological assessments (52.1%), interviews and consultations (50.1%), supervision and training (9.1%), and others (6.7%).

Clients for the services of clinical psychology can be categorized into the following age groups: children and youths (58.7%), middle aged people (55.0%), college students and working youths (41.7%), infants (39.6%), and the elderly (18.4%). Given the large number of the elderly people in Japan, 18.4% is a rather small figure for clinical psychology services, especially when we consider the fact that about 7% of those aged 65 and older are reported to have mental disorders.

Bullying in Japanese schools is a serious problem which has come to light. Due to the increasing number of cases of bullying, a school counseling system has been planned and discussed since 1995 for future implementation by the Ministry of Education. Appreciation for clinical psychology has started to permeate Japanese society owing to this problem. Clinical psychologists have also started tackling the pressing issue of HIV counseling. Furthermore, systems for crisis intervention such as the "Lifeline" system have gradually been put in order. It must, however, be pointed out that only a few elderly are taking advantage of these services. This is because they tend to think that revealing a personal psychological problem to a stranger is shameful. Also, they are not used to paying money for such intangible services as counseling.

2.40.2 SPECIFIC PSYCHOLOGICAL PROBLEMS IN JAPANESE OLDER ADULTS

2.40.2.1 Psychological Disturbance in Old Age

The Ministry of Health and Welfare conducted a survey on outpatients according to the *ICD-9* (*International statistical classification of* *diseases and related health problems-ninth revision*) in 1993 (Japanese Ministry of Health and Welfare, 1995).

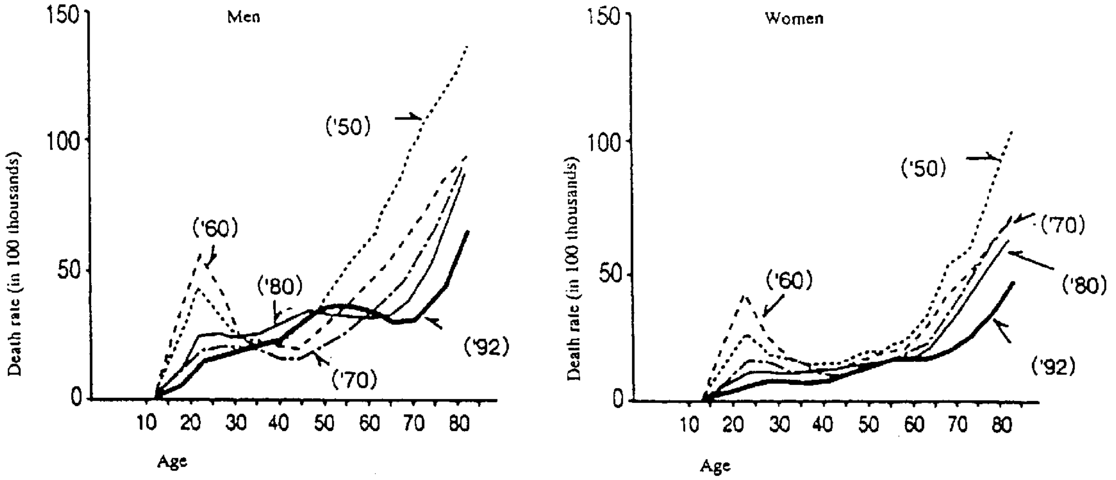
The highest number of older adults sought treatment for senile/presenile organic psychosis (senile dementia) (43%), followed by neurosis (33%), and manic-depressive psychosis (26%). There is a tendency to consider depression as a more serious problem than neurosis among the aged, however it is evident from the above figures that the threat of neurosis should not be ignored (Japanese Ministry of Health and Welfare, 1995).

Figure 2 shows trends of outpatients by age group suffering from neurosis and manic-depressive psychosis. The curves for neurosis show a difference between the numbers of male and female outpatients receiving treatment. The peak for women is in the 70–74 age group, but not much difference among age groups exists in the men's curve. Little difference can be seen between the curves for men and women for manic-depressive psychosis, and the peak for both is in the 70–74 age group.

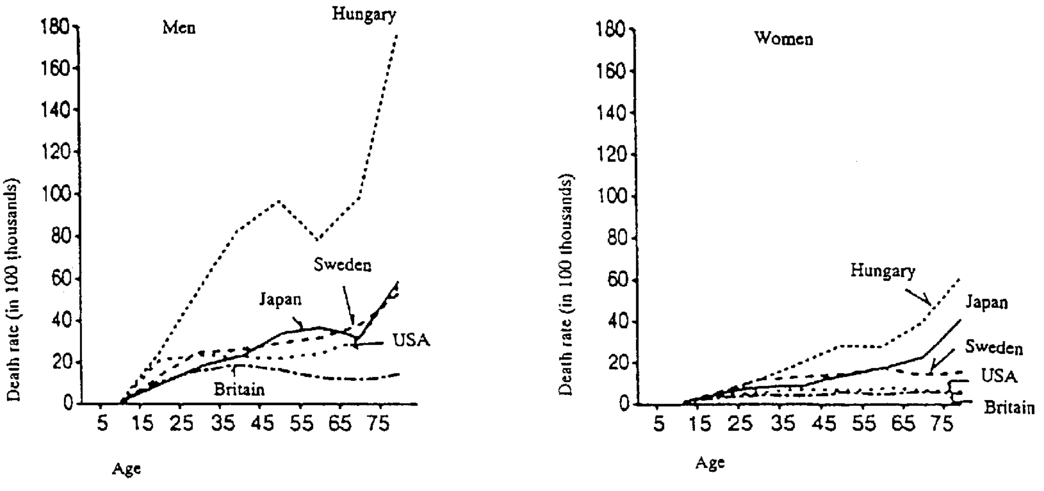
The results of this survey suggest that there is more chance of suffering from psychological disorders during the period from middle age to old age than at any other time in life. However, clinical services for these people are lagging behind the services available to younger people.

2.40.2.2 Suicide Among the Elderly: Aspects of Suicide Unique to Japan

Figure 3 (Association for Health and Welfare Statistics, 1994) shows trends of the suicide rate



Changes in Suicide Rate in Japan



Cross-national Comparison of Suicide Rate

Figure 2 Suicide rate of elderly people: changes in Japan and cross-national comparison.

in different years by age group in Japan as compared to other countries. Although the suicide rate of people aged 65 years and older is declining year by year, it is still the highest among all age groups. The graphs comparing suicide rates of people aged 65 and older in different countries show that Hungary has the highest rate for both men and women, and that Japan has the second highest for both men and women. The leading cause of suicide among the elderly is illness (70%), followed by family problems, alcohol dependency, and psychological disturbance. Few suicides result from financial difficulties. This suggests that many older adults are suffering from illness or facing problems with their family while they are living in relative affluence. Older adults commit suicide because they "don't want to be a nuisance to the family." Committing suicide is not considered a sin in the religious views of most Japanese. The same can be said of double suicides of married couples which are discussed in this section.

What is considered a double suicide of a married couple is not the same in Japan as it is the West. Husband and wife mutually agree to commit suicide, or, in some cases, one spouse kills the other and then commits suicide. It must be understood here that Japanese people do not consider the murder/suicide of a married couple to be any different from a double suicide. Unlike the prevailing views in Western culture, this kind of murder/suicide is classified along with double suicide due to some profound cultural differences between Japan and the West. Older couples in Japan do not consider their spouses as individual persons, but rather as a part of themselves. Together, they are an inseparable whole, or "one flesh." This idea stems from the traditional Japanese concept of the extended family system. Older Japanese couples try to solve their problems by themselves, without outside help. When considering suicide, they tend to think, "It is better for my wife (or husband) to die with me, rather than for me to leave her (or him) alone to suffer." This attitude, while common in Japan, may be difficult for Westerners to understand.

Although cases have been few, murder of elderly people by a family member caregiver has become a social problem. In 1992, for example, there were 20 such cases, 17 of the victims being women. The murders were committed by husband or wife (9 cases), son or daughter (10 cases) and daughter in law (1 case) (Takeda, 1994). In most of the murder cases, the task of caring for the elderly had been done entirely within the family without the help of others or public service organizations, and thus, the caregiver's mental and physical fatigue had reached its limit.

2.40.2.3 Elderly Abuse: Abuse and Neglect

There is little substantiated data on elderly abuse in Japan due to the fact that people have been reluctant to discuss the issue. Tanaka (1994) surveyed 400 At-home Elderly Care Support Centers throughout Japan. These centers act as coordinators between families or older adults and public service organizations. The survey was conducted via mail and 220 replies were received (55%). Seventy-two of the respondants reported elderly abuse as one of their items for consultation.

What seems characteristic in Japan is that if elderly abuse is divided into abuse and neglect, there is more of the latter. The ratio of abuse, as opposed to neglect, was 75.1% in New York, 84.4% in London and 43.1% in Japan nationwide. This means that neglect made up more than half the cases of elderly abuse in Japan. In common with Western countries, more women are abused than men and the abuse rate increases with age. It is unique to Japan that most cases of abuse are committed by family members, and also that the abuse rate increases as the caregiver's age increases. The main cause of abuse is the fatigue associated with caregiving.

2.40.3 PSYCHOTHERAPEUTIC APPROACHES FOR THE ELDERLY IN CLINICAL GEROPSYCHOLOGY

Although the number of research papers presented at the Congress of the Association of Clinical Psychology has been increasing, much less research has been done with elderly people. This is due to the fact that gerontology has only recently been introduced and research into gerontological clinical psychology has not yet been established as a field in Japan.

The first and only gerontological research center in Japan, the "Tokyo Metropolitan Institute of Gerontology," was established in 1972, just before the population of people aged 65 years and older reached 7%. This is when research into the psychological characteristics of the elderly first began. Shimonaka and Nakazato (1980, 1986) compared personality characteristics of elderly people with those of young and middle-aged adults using a sentence completion test. With respect to family relationships, elderly people gave more positive responses to family images. As for self-perception, elderly people perceived their past and present selves as being more positive while the younger

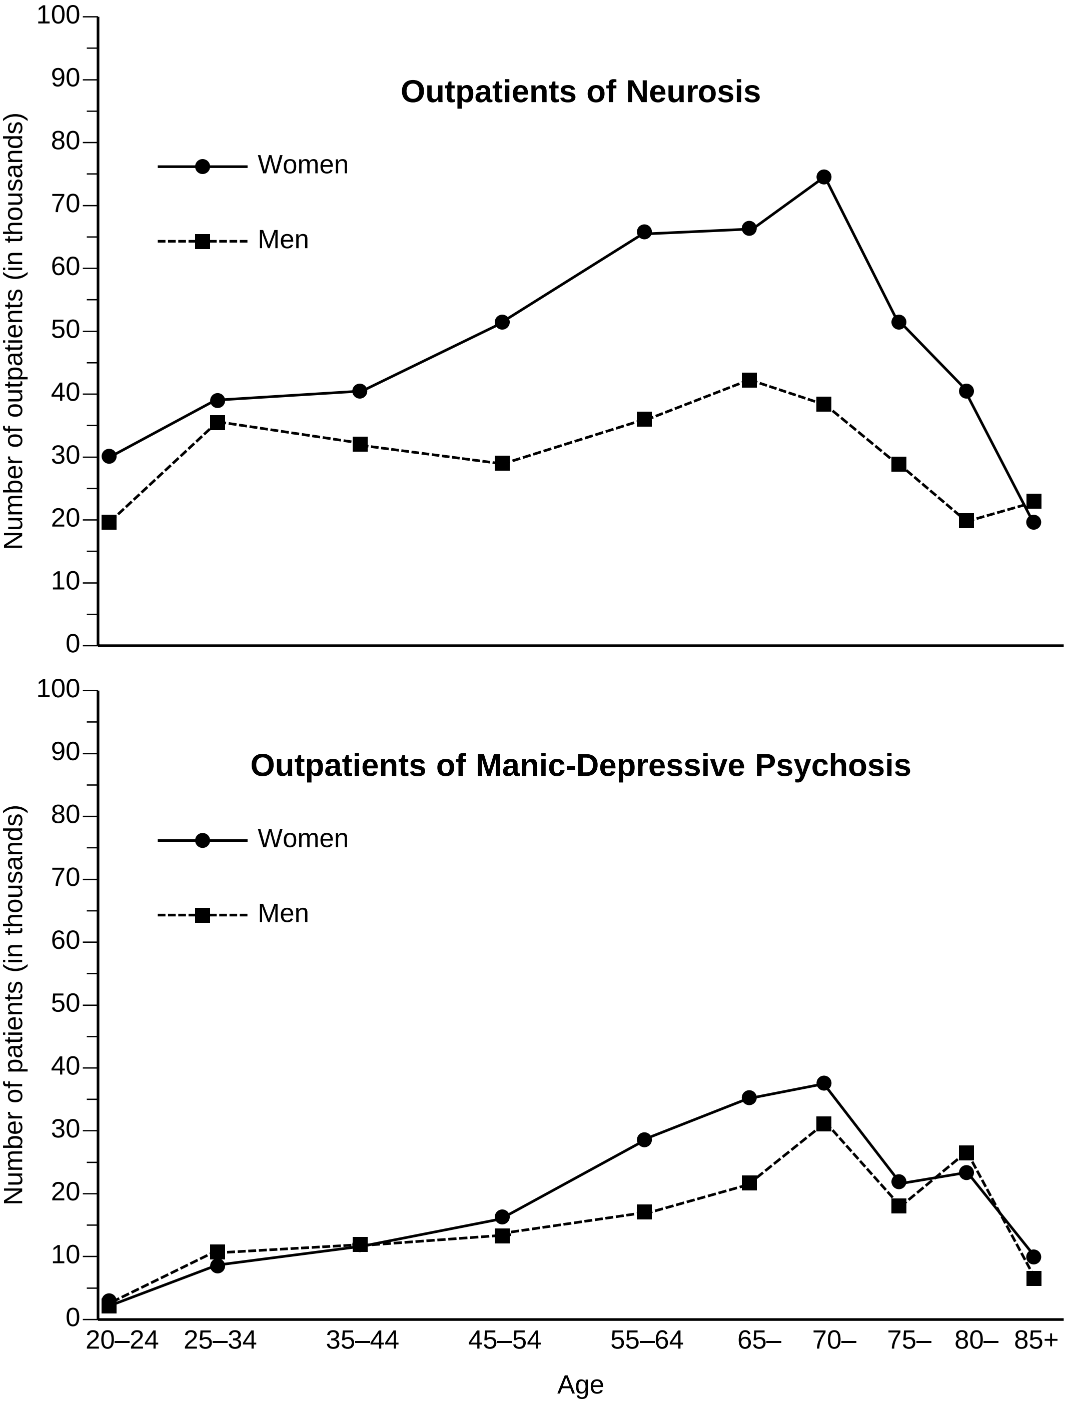


Figure 3 Number of outpatients of neurosis and manic-depressive psychosis according to age group and sex.

generations perceived their future selves as being more positive. However, future self-perception for elderly people was limited by the ultimate finality of death. More young adults viewed death with negative feelings such as fear, sorrow, or distress than did the older adults, who saw death in a neutral manner, as destiny, or a natural phenomenon.

Furthermore, in order to investigate stability or change in personality from young-old age to old-old age, a survey, which had been given to 70 year olds living in the community, was followed up 10 years later (1976–1986). It was revealed that positive family image increased with advancing age. With respect to self-perception, the past self changed from objective to positive. The present self maintained positive responses, while the future self shifted from objective to negative (Shimonaka & Nakazato, 1989).

The Rorschach Inkblot Test has often been used to analyze the personality of the elderly in Japan. Shimonaka and Nakazato (1991) used the Rorschach Inkblot Test six times over a 10 year period to study changes in personality related to aging and to determine whether significant changes in personality precede death.

Age-related changes were observed in the number of responses, responses regarding rejection, shading and popular, poor form level, and content range. Changes in these variables suggest that productivity, creative thinking, cooperativeness, and concern for and interest in society lessen with advancing age. Over the four to six years preceding death, popular responses and content range declined, with the decline accelerating near death. Tests given within two years of death showed less animal movement response, higher form (F(−)%), and higher human content. These results suggest that productivity, vital energy, and ego strength become reduced prior to death, while interest in and sensitivity to others is maintained to the end (Shimonaka & Nakazato, 1991).

People are inclined to have a negative image towards aging. This tendency was especially strong during the 1960s and 1970s. During this time, old age was considered to be a time of much negative change and anxiety (Cattell, 1965; Jarvik & Russell, 1979). However, from the results of the life-span developmental approach regarding anxiety (Costa et al., 1986), it has been suggested that feelings of anxiety decrease as age increases.

The anxiety of Japanese adults aged between 25 and 92 years was measured using a Japanese version of the State–Trait Inventory and found that the level of anxiety lowered linearly as age increased. These results suggest that anxiety about death is not, as expected, especially strong in old age (Nakazato & Shimonaka, 1989).

Psychotherapy for elderly people by clinical psychologists in Japan is quite uncommon. Since the 1980s, however, more effort has been made in this regard at institutions and day care centers for the elderly, as the population of the elderly has been increasing. This has been mainly group therapy, and there has been no reported research on behavior, cognitive, or family therapies yet. Moreover, many of the research papers available use results based on case studies and subjective evaluations by practitioners. Since most subjects of group therapy are those with senile dementia, reality orientation, reminiscence, and therapeutic recreation are the main activities provided. This is probably due to the fact that the drastic increase of people with senile dementia has become a social problem in Japan. Since these group therapy activities had not been used until 1990 in Japan, many research papers mainly examine their effectiveness.

The effectiveness of reality orientation has been examined using as subjects people with moderate senile dementia in a nursing home. Changes in the dementia scale (Hasegana, 1983; Kahn, Goldharb, Pollack, & Peck, 1960) were observed before, just after, and six months after the orientation. The participants showed improvement in the dementia scale scores, unlike the control group, which showed no change.

Furthermore, according to the evaluation of daily behavior in the ward by the charge nurse, improvement was seen in social communication. The improved dementia scale scores were even maintained six months after the orientation. These results suggest that reality orientation is very effective at the early stages of dementia (Shimonaka & Nakazato, 1989; Shimonaka, Nakazato, Habu, Haga, & Mizuno, 1988).

The effectiveness of reminiscence, which is as common as reality orientation in countries other than Japan, was examined with inpatients of a psychiatry ward as subjects, and evaluation was made using the Moses scale. Moses scale scores showed improvement after reminiscence. These results suggest that the psychological state, relationships with others, and the level of independence among people with senile dementia was improved by participating in reminiscence (Kurokawa, 1995).

There have been other reports on the effectiveness of therapeutic recreation incorporating play therapy, art therapy, sports therapy (Kawamuro, 1995; Koike, 1995; Sadaki, 1993), and music therapy (Kitamoto, 1996) which are carried out at geriatric hospitals, day care centers, and nursing homes.

Finally, there has been a unique approach, in which group therapy, provided during day care for outpatients with senile dementia who are receiving care at home from their family, is combined with group counseling provided for the outpatients' family members. This attempt aims to vitalize the residual mental functions of people suffering from senile dementia whose activity is restricted to their homes. At the same time, family members who are exhausted from care giving are provided with rest time and group counseling (Kato et al., 1987).

The various therapies above for people with senile dementia have just been introduced in Japan and they are still at a stage where their effectiveness is being researched. Storandt, Siegler, and Elias (1978) have pointed out in *The clinical psychology of aging* that there were too few clinical psychologists for people aged 65 and older. Despite the fact that 10% of those aged 65 and over were in need of some kind of mental health services in the US at that time, clinical psychology had long neglected the treatment of older adults. In the mid-1990s Japan is in the very same situation. Although there are few clinical psychologists in Japan, their efforts for proper application of therapies to the aged today will bear fruit and become a touchstone for tomorrow's clinical psychologists for the aged.

2.41.1 INTRODUCTION

The development of knowledge and its application occurs within a social construct. As such, a discipline is both influenced by the society in which it lives and, when that knowledge is disseminated and applied, it influences that society. This dynamic is especially true for a discipline like psychology, and very particularly clinical psychology, which has so much to contribute to issues of national and global concern. For example, the results of a massive new assessment of the world's state of health, and of the changes it is likely to undergo between 1997 and 2020, underscores the role of behavior in maintaining a healthy citizenry (Murray & Lopez, 1996). This study reports that the most overlooked cause of death and disability is injury, specifically using the word "injury" rather than "accident" in order to communicate that injurious events are avoidable. They note that the most important single variable expected to impact the world's health in 2020 is the use of tobacco. In a ranking of conditions purported to cause the greatest disease burden, severe depression moves from fourth highest in 1990 to second highest in 2020.

These data and their projections suggest that the discipline of psychology, especially through its subfield of clinical psychology, should be at the forefront of healthcare, and through these contributions valued highly by the society in which it lives. A prominent measure of the national status of the discipline is the support of that discipline in the corridors of national governance. For psychologists in the USA, this means looking at the perception, knowledge, and support for the discipline from members of the US Congress: members of the Senate (Senators) who represent their states each term for a period of six years and members of the House of Representatives (Representatives) who represent their districts (within each state) each term for a period of two years (despite much discussion about limiting the number of terms a member may serve, no action has ever been passed to do so). A second source of support and hence a measure of status lies in the Executive branch of government which through its agencies implements the legislation and policies set by Congress. It is through these governing bodies that the larger society identifies its interests, expresses its values, and develops the means to meet its national needs.

The role of advocacy in society's perception of psychology cannot be underestimated. This role is enlarged by the dynamic nature of advocacy which works to recognize psychology's potential to contribute to areas of national need and in so doing further reinforces the need for psychology's contributions to society. By definition, "advocacy" involves "pleading or defending the cause" (Webster; 1995), in this case, the cause of psychology. Thus, when advocating on behalf of psychology, one educates policymakers and implementers about the value of the discipline and hence the need or right of the discipline for support, resources, recognition, status, and the like. At the national level, most often advocacy involves working with policymakers and their staffs in Congress, and/or the implementors of these policies, the staffs in the various federal agencies.

In this chapter, the process of advocacy will be described, with its critical variables, and how these factors, together with existing structures for advocating, serve to enhance or hinder successful advocacy on behalf of psychology, in particular, utilizing examples from advocating for support for education in professional psychology. Moreover, as the advocacy process by its very nature is a changing one, emphasis should be placed on patterns rather than particulars as the specifics can be expected to change quickly and often.

2.41.2 THE NATURE OF ADVOCACY IN THE POLITICAL PROCESS

2.41.2.1 What is Advocacy?

The democratic process is one in which complementary and competing interests must vie for recognition and, through that recognition, for control and resources. Whose interests and which factors are recognized might be thought to be determined logically by the nature of the issue. But whose understanding of the issue and which priority among the many possible will prevail? How the policymaker understands the issue, its component parts, and what interests or factors are thought to be critical to the matter being deliberated necessarily is in the eye of the beholder. Thus, when advocating on behalf of psychology, that is, when pleading the case of the discipline, in effect the listener is being educated about the ways in which psychology can contribute to the issue at hand. To be effective, this must be done in ways that are meaningful, of interest, and value to the listener, and true to the discipline. In the political process, with its broad range of interests and decision making, this means that the job is to demonstrate to the listener, the policymaker, or legislator why and how psychology can serve the national issue being considered. Of course, the particular issue varies. Given the US national legislative agenda with its attention to healthcare, and the potential of clinical psychology to contribute to this agenda, the conversation is most likely to focus on one of the six major areas of health that have been demonstrated to be behaviorally based: violence, substance abuse, smoking, injury, diet, and AIDS. The goal then is to have the listener recognize that psychology has a significant contribution to make, so that when funding is being allocated or professional fields identified for inclusion in a particular practice or intervention, the listener will conclude that psychology should be a part of the policy and so named in the legislation. At the very least, the goal of advocacy is that the legislation should not preclude or deny psychology's participation in the bill being considered.

2.41.2.2 Why is Advocacy Necessary?

Ideally, advocacy is necessary for the same reasons that any education endeavor is necessary; so that the policymaker will have the benefit of the most pertinent information to the task, that is, so that the issues faced by legislators will have the benefit of the contributions of the discipline. In this scenario, the best the discipline has to offer is put forward to a particular cause and the results left to the good judgment of the legislators. But the political process is not always so ideal. There will be many ways to meet the demands being deliberated, many interests involved, and limited resources available for allocation. In these cases, advocacy also serves to bring attention and recognition to psychology. In the US political process, if there is no advocacy on behalf of the discipline, psychology is unlikely to be recognized. Herein lies a particular problem for clinical psychology in the complex and crowded healthcare arena in the 1990s.

This problem arises from the very nature of the discipline being a field with numerous subfields. It is not well understood by the general public. Among those who do know the discipline, some know psychologists as mental health practitioners; others are aware that psychologists are behavioral scientists who conduct research in areas like cognition and neuroscience; and still others remember their psychology professors from undergraduate courses in personality and perception. Yet often these separate parts are not a coherent whole, able to bring the full strength and richness of the discipline to bear on the range of policy matters before Congress. Moreover, in the process of advocating for a particular issue, and needing to keep the message simple, most often only a limited part of psychology will be addressed, for example, the needs of practice or the particular implications for science. Thus, despite the many roles that psychologists actually serve, there remains a limited public understanding of psychology as a whole and the many ways in which the discipline can be applied to real issues of public concern and national need: a fact that unfortunately is as true for policymakers as for the general public.

2.41.2.3 Who Does Advocacy?

There are many answers to this question. On the most general level, while this answer may come as a surprise to the reader, in fact, everyone in the discipline advocates. The problem of course being that psychologists are unaware that in the process of their work, they also serve to educate others about whether or not this work is valuable, deserves public recognition, support, and sometimes even protection. In spite of the lack of awareness, whether in classrooms or offices, how the discipline is presented, to whom, and with what level of respect and value will greatly influence how the listener will view the discipline now and in the future. Perhaps the most misunderstood arena for advocacy are classrooms where the citizens of tomorrow are most likely to be introduced to the discipline and its potential to contribute to areas of national need. If psychologists do not show respect for the discipline as a whole, others can hardly do so. If psychologists do not demonstrate how their knowledge base can contribute to national need, others cannot do so. And if the value and application of their work to areas of national interest are left unspoken, then these citizens, or their representatives, cannot be expected to allocate national resources to support psychologists' education, science, or practice.

On a more direct level, of course, advocacy follows a planned strategy, developed by professional lobbyists working with psychologists and focused on policymakers involved in issues of particular interest to psychologists, whether these be in the areas related to education, practice, science, or public interest. This approach, necessarily focused and targeted, remains dependent on the participation of psychologists at every level and activity as will be delineated as the process of advocacy for psychology is described.

2.41.2.4 What Makes Advocacy Effective?

Effectiveness is based on the same factors that make any human interaction effective: clarity, consistency, context, and credibility. Advocacy is not accomplished through magic nor are advocacy skills acquired through academic study. Advocacy, while a learned behavior, must be expanded through experience and perfected by practice. In other words, if advocacy is examined for its key elements, the most basic skills of human interaction will emerge. These skills then must be augmented by knowledge of the discipline, motivation to succeed, much persistence, and a little bit of good luck.

Some compare the components of successful advocacy to those of actual warfare, in this way placing key factors into the framework of a battle. Whether or not warfare is considered effective human interaction is debatable. However, the analogy serves to focus attention on the importance of reaching a conclusion in a competitive environment. At times, the analogy seems apt; the competition is real and the desire to win is strong. Zorack (1990) reports that the lobbying process parallels those factors developed by British Major-General J.F.C. Fuller during WWI as elements of a successful combat campaign:

(i) objective—clearly define an attainable goal,

(ii) offensive—exploit the initiative, be proactive, not reactive,

(iii) mass—concentrate efforts at optimum time and place,

(iv) economy of force—focus on one initiative at a time,

(v) maneuver—place opposition at disadvantage,

(vi) unity of command—maintain one leader,

(vii) security—know what information to share and what not to share,

(viii) surprise—employ unexpected legislative maneuvering when possible, and

(ix) simplicity—simplify and limit all requests.

The above-mentioned tenets for a successful campaign, regardless of the battlefield, are self-evident if advocacy is conceptualized as a campaign and the delivery of the discipline as the artillery. For this advocacy battlefield, the message is to recognize the need and value of psychology to society thereby establishing its right to support, recognition and involvement in legislation, and its implementation. In this view of the advocacy process, emphasis remains on the importance of communicating effectively, most often to individuals with little knowledge of the message and with great need to act efficiently and effectively for a broad range of very vocal constituents. Psychologists, especially, should be able to utilize their understanding of perception, memory, problem solving, social interaction, motivation, and the like to develop effective strategies for advocacy.

2.41.3 ADVOCACY: IN ACTION

2.41.3.1 Advocacy: Goals and Plans

Successful advocacy requires a plan of action consistent with the goal. As an example, the overarching goal for education is to increase federal funding for education and training programs in psychology. But there are many ways to go after this larger goal: through new legislation, by revising existing legislation to more effectively include psychology, or by changing regulatory language that controls how the legislation is implemented to name the most likely target areas. Careful analysis of the range of legislation that it is possible to effect, the likelihood of success, the ability of the results to benefit the discipline, as well as the more practical factors of time, cost, and resources will determine the particular target initiative. Because advocacy resources can rarely match the range of possible initiatives, priorities must be established. Within the American Psychological Association (APA), priorities are first established for Education by the Board of Educational Affairs with assistance from the Education Directorate and the Public Policy Office. Once the priorities are set for education, they are then tested with those of the other Directorates to achieve oversight, coordination, and priorities for the association as a whole. For example, in 1996, opportunities were available to impact the Higher Education Act and the Public Health Service Act as both were being reauthorized during the 105th Congress. Thus, it was decided to target, as the primary advocacy goals, expanded eligibility and increased participation for psychology in these bills.

Choice of a particular target initiative determines where the strategy will be focused since political combat may take place in either the legislative or executive branches of government. Although education advocacy is focused primarily on Congress and the legislative process, it sometimes targets the Executive Branch around the promulgation of regulations, thereby seeking to establish a positive and productive relationship with agency officials who administer the programs in which psychology participates. The two priority pieces of legislation for education, both in the reauthorization process, focus the strategy on Congress, particularly the members of those committees with jurisdiction over these bills who make final recommendations for action to the full Congress.

With the goals established and targets identified, education advocacy first develops a clear message. An information strategy was employed to educate the chairs and members of relevant committees and subcommittees in the Senate and House of Representatives about psychology's ability to meet national needs. If psychology is seen as important to the nation's well-being, then the education of psychologists should be supported by federal funds. In order to educate and thus garner support from these key legislators, two sources of information are needed. First, clear, databased, and well-presented information is necessary to establish psychology's contributions to national needs. In choosing from among the many possible topics for this information base, areas of interest and meaning to the audience should be sought and found. So, if the Chairperson of the Committee is very interested in health, say cancer treatment, then demonstrating psychology's role in meeting these particular needs is likely to be of great interest. Thus, topics are chosen and data and other relevant information about psychology's contributions to these topic areas are gathered from publications, the APA Research Office, federal agencies, and other sources to develop concise and clear informational materials. In making the case, psychology's ability to contribute in significant ways to the topic area must be demonstrated, but also the value and contribution of psychology must be established through benefit-analysis and cost-effectiveness data. Particularly, but not exclusively, in the 1990s healthcare arena, these two factors are dominant in considering the value of a discipline's ability to contribute.

Further, since psychology is not yet firmly established in the public's mind as a health profession, and certainly not as "primary care," efforts to justify and promote the contribution of psychology to healthcare are critical to successful advocacy. Awareness must be increased about clinical psychology's unique contributions and expanding knowledge, not only as mental health providers, but especially as behavioral health professionals. The reason for this emphasis is twofold. First, it is consistent with the work of many in the field; there is much for psychology to contribute as a behavioral health provider. Just as important is that behavioral health is consistent with the view policymakers have of healthcare in the 1990s and as they expect it to evolve in the twenty-first century. This approach points out that in making the case, it must be understood how listeners understand the issue and fit the discipline's work, worth, and contributions to that perspective.

Fortunately, this fit is often not difficult to make, but it must be remembered to take the time to do so. After all, the sign of a good educator is to begin at the student's level of knowledge and understanding and build from there. Knowing that the policymaker understands and values the role of behavior in healthcare sets the stage for placing clinical psychologists' unique contributions as educators, researchers, and practitioners into that context. In other words, the advocate starts with the perceptions of those making policy, understands how to fit the discipline into their national priorities, and elucidates what they need to know about psychology in order to make the relevant connections to garner their support.

Once the primary message of how the discipline can contribute to the area being considered and the value of psychology as a cost-effective player is established, then the advocate can move on to another essential aspect of the advocacy message which is to educate policymakers about concerns and interests of psychologists. Until this point, the advocate has been educating the policymakers about how the discipline meets their needs. Having achieved that part of the message, advocates move on to explain what the discipline needs in order to be able to continue to make these important contributions. This might be funding for education and training of a new generation of psychologists or new skills for the current cohort; support for continued research and new knowledge, or inclusion as providers of healthcare, eligible to access programs of federal support for healthcare.

2.41.3.2 Advocacy: Making the Connection

With the message developed and packaged, how to present it must be determined, coordinated, and implemented utilizing as many formats as possible, delivered by those most relevant to the audience: their constituents, the voter; their expert constituents, the psychologist voter; and finally national experts, the lobbyists and staff of national associations, in that order of importance and credibility. At the same time, it is the national experts whose full-time job is to advocate. The remaining participants are volunteers working within limitations on time, resources, and advocacy expertise and "the lobbyist who has the access has the best opportunity to wield the most influence" (Zorack, 1990). It is critical to establish rapport and a positive relationship with key legislators and their staff. A positive, ongoing relationship has implications for present and future legislative initiatives. The relationship must be based on honesty and trust, be mutually beneficial, provide expertise (directly or indirectly) and ensure constituent support.

Establishing a relationship with staff and/or legislator is accomplished primarily through visits to policymakers at the national, state, and local levels. Congressional briefings on a particular subject of interest to legislators and their staff, as well as site visits to places of interest in their districts/states, are also helpful in establishing relationships. Keeping in touch with staff by telephone is another important way to maintain ongoing communications. As members of Congress begin to use Internet, that will be another important and far easier method of communication for advocates. The use of fax machines and email, in fact, has revolutionized communication that needs to be timely and efficient. However, too much contact (e.g., phone calls, faxes, or email) can also be a serious nuisance to busy staff and legislators, and at times highly detrimental to one's efforts.

Constituents communicate best through visits, phone calls, and letters. In fact, constituent mail is still the most effective means of influencing how a member of Congress votes. The other is supporting members of Congress in their fundraising efforts to be re-elected, especially members of the House of Representatives who must run for office every two years. When thought of in terms of educating these members, consistency is a worthwhile investment.

Finally, successful connections result from a multifaceted strategy. Especially if the message is a new or unfamiliar one, it will benefit from several hearings, different perspectives, and several messengers. Thus, a successful strategy will depend not only on the ability to know what actions are needed, but ultimately on their implementation. Some initiatives will require working with one or more associations in a coalition, some will involve taking the message directly to the legislator, while others demand working with some or all of the committee staff, and some may need an accompanying public relations campaign while others will require a one time Congressional briefing. Of course, the quantity and quality of activities undertaken to meet an advocacy target initiative must be consistent with the availability of resources and time.

2.41.3.3 Advocacy: Process or Outcome

Following any policy issue in the popular press makes it obvious that legislation and policymaking are ongoing processes. So too is advocacy. Thus, it makes sense that establishing and maintaining relationships with legislators, staff, and agency officials must be a continuous process. This recognition makes the determination of the outcome of a particular advocacy initiative unclear, especially when working with the legislative branch. Therefore, it is unwise to measure the success or failure of a legislative initiative on whether or not a particular advocacy goal is achieved at a specific moment in time.

Indeed, federal legislative initiatives are unpredictable, especially when dealing with enacting or reauthorizing legislation. Even though budget and appropriations legislation occur according to a defined cycle, their underlying legislative processes are unpredictable such that along the way any anticipated outcome is far from certain; it is simply not done until it is done. In fact, as the entire legislative process becomes subject to greater political influences and tensions between the executive and legislative branches of government, it becomes ever less certain what is going to happen or when. For example, during the first session of the 104th Congress, the Republican-controlled House and Senate could not come to an agreement with the Democratic Administration on funding federal programs. As a result, 15 separate Continuing Resolutions were enacted to allow federal programs to continue during this fractious period. However, with each enactment of a Continuing Resolution, programs were targeted for a set percentage reduction in funding with no opportunity to change any other part of the legislation.

Certainly, enacting or reauthorizing legislation is the most uncertain process to effect, as thousands of bills are introduced each session but only a handful are enacted into law. In fact, as demonstrated in the above example, even those bills being reauthorized (i.e., those bills requiring review and extension) are not necessarily acted upon within the term of Congress specified for reauthorization. A good example is the effort to reauthorize the Public Health Service Act during the 103rd Congress. It passed both Houses of Congress, and was approved in conference by both houses. However, at the last minute, only the full House gave the bill its final *pro forma* approval; the Senate did not. Thus, the Public Health Service Act remained unchanged. The Senate Republicans looking to the November 1994 elections, when the Republicans made sweeping victories and took control of both Houses of Congress, did not want to give President Clinton even one small success regarding healthcare legislation. This result was most unfortunate for psychology because the proposed revised Public Health Service Act legislation had contained a hard-won provision to set aside funds for the education and training of minorities in psychology. As a result, this piece of legislation remains a high priority for education advocacy efforts, five years and three sessions of Congress after first beginning this work.

In summary, getting a bill drafted is the easy part, getting it passed is next to impossible. In fact, getting a bill through Congress takes an enormous amount of time and effort. Amending a piece of legislation depends on whether or not the statute is up for consideration (i.e., reauthorization), as well as what the proposed amendment(s) contain. It must be emphasized that the least amount of change, coupled with its degree of simplicity, positively effects its chances of being accepted.

Advocacy efforts regarding federal regulations are the easiest to control, which is not to suggest that they are easy. For instance, providing feedback to the agencies promulgating regulations happens according to a schedule and usually results from a consensus, that is, getting those who have a vested interest to agree with how a program is to be implemented. Working with agencies to direct more funds and attention to a specific field (e.g., psychology), or to place representatives of the field on advisory bodies, is much more challenging and far from certain. An example from education occurred, during the 103rd Congress, when the Bureau of Health Professions (a program authorized by the Public Health Service Act) chose to focus primarily on increasing the number of ethnic minority physicians. With decreasing federal funding, the Bureau of Health Professions was not interested in increasing the number of psychologists in the programs without first receiving an increase in funding. For this reason, education advocacy efforts to work with the agency to include psychology in their programs became a notable challenge. It is pleasing to report that this has met with continued success. This success has been gained in small steps over several years with still some distance to go before the goal will have been reached. Each step has required ongoing connections with the agency's staff, maintaining their attention to psychology's needs and psychology's ability to support their agency's mission and goals. Finally, along the way it is necessary to be sure that the agency's staff is cognizant of the links between Congressional decisions as evident in legislation, psychology's constituents, and agency implementation.

All of this serves to underscore the importance of having a clear and well-marked strategy, one that serves as a road map for a long and at times frustrating journey. Detours along the way must be expected and markers established against which to measure progress and ensure that the journey remains on track. Like any journey, separating process from outcome along the way can be distracting and miss the point. In the advocacy world, advancing the cause of psychology may occur in spite of missing any particular legislative target, and that advance will serve well in the next round of legislation and policymaking.

2.41.3.4 Advocacy: Cost, Competition, and Champions

As has been described, achieving advocacy goals may take years to accomplish during which time consideration of cost, competition, and champions are most relevant. Lobbying is of little consequence if the advocacy plan or activities lack organizational support that translates into real dollars. The more resources available, the more extensive and thorough the advocacy. Unfortunately, there is no consistent relationship between the amount of money spent and the likelihood of success. No matter, it is also always true that without adequate funding, the scope of advocacy goals and expectation for success must be limited from the start. Funding is needed for professional staff to create and prepare information materials, to contact and prepare psychologists' advocates, to organize and assist in the delivery of the advocacy message, to fund the necessary trips, and related support of the myriad of advocacy activities that are part of successful campaigns.

The cost of an advocacy initiative will be dependent not only on the expected activities of the initiative but also on the extent of competition or opposition encountered along the journey. For example, current beneficiaries of existing legislation often do not want to share the limited federal dollars that would result from adding psychology to the recipients of federal support. Also, it is not uncommon to find that there are those who want funds directed to their legislative priorities and away from others. Whatever the reason, the competition must be addressed and that requires more time, effort, and money. For example, opposition from others in the healthcare community during the Public Health Service Act debate resulted from their reluctance to share limited, and dwindling, federal funds. That particular obstacle was removed by forming a coalition with other professionals in the healthcare community to advocate jointly for issues of mutual interest. What was most effective in establishing this coalition was educating the healthcare community about what psychologists do, convincing them that together, better healthcare can be provided, each complementing and supplementing the other professional services. Nevertheless, in the competitive arena of healthcare, opposition from the medical community and others will remain a challenge for psychology to confront; each aspect will need to be addressed and argued one on one, for a long time to come.

Competition and opposition are constant companions of the advocacy process. As outlined, there are many stages in the legislative process. Each one presents an opportunity to block your competitors and likewise to be thwarted by them. Congressional champions are the single most significant factor in meeting these challenges. Especially when the opposition is stiff, a powerful legislator serving as your champion can be the deciding factor. Champions and supporters of the proposed advocacy initiative are critical to advancing the cause: it is extremely difficult, likely impossible, without them. These champions not only bring the message to the floor of Congress but also shepherd the votes of other policymakers in your favor.

2.41.3.5 Advocacy: The Uncontrollable Element of Time

Timing is everything. If one waits too long in the political process before presenting a case, there will not be sufficient time to carry forth the message through letters, visits, and testimony. As the voting nears, legislators, and their staff are frenzied, unwilling, and unable to process new information, especially information that will upset delicate balances built among existing constituents. But if a proposal is presented too early, it may be shelved by the legislators and/or their staff, forgotten in the midst of more pressing matters requiring immediate attention. Lobbyists must monitor their contacts with legislators and staff; no one likes someone who usurps their valuable time. Nevertheless, unless calls are made regularly to legislators and staff, it is easy to miss important opportunities to plead the cause. For example, a hearing on a particular bill provides an excellent opportunity to have a psychologist testify in Congress, in this way publicly making the case for the discipline to all Committee members.

The length of time to accomplish an advocacy initiative is the most uncontrollable of all aspects of advocacy. Indeed, complicated initiatives must be considered for the long haul, that is, more than one session of Congress, often several years (note: one session of Congress covers a two-year period). For example, the Public Health Service Act reauthorization entered the first session of the Congress, approximately five years after the initial efforts to reauthorize that legislation. Moreover, all along the way it is necessary to compromise, increasing the chances of getting less than what you at first wanted, and probably concluding with something quite different from what you first set out to accomplish. Nevertheless, as noted above, there are tangible benefits from the process during these long initiatives: educating policymakers about issue and discipline, establishing a positive relationship with key legislators and their staffs, and through this work garnering their support for psychology that will serve well for future endeavors.

During this time, however, the larger political context will change, a factor directly effecting the political process. Prevailing national priorities do not remain constant. Variables such as fiscal strength and social climate, whether real or perceived, national or international, impact what happens in Congress by influencing the policymakers' receptivity to your ideas, messages, and needs.

2.41.3.6 Summary

Successful advocacy is a complex, multidimensional process requiring discipline and flexibility, vigilance, and strategic action. It requires ongoing involvement by psychologists who often understand neither the reasons for their participation nor the process. Finally, vicissitudes of time act to introduce a level of uncertainty and lack of control particularly frustrating to the uninitiated. In all, for so important an activity, it is fraught with barriers to its success. Coordination, knowledge, experience, and motivation are key to meeting these challenges.

2.41.4 THE ADVOCATES

2.41.4.1 The Constituent

As Tip O'Neill, a legendary Speaker of the House of Representatives for over 15 years, was frequently heard to say: "Politics is people." Without question, the key player in any advocacy initiative is the constituent (individually or collectively). Individually, each constituent is important because they vote to elect the legislator, something that is especially significant to members of the House of Representatives who must stand for election every two years. Understanding this, many psychologists are politically active and play a role in the political process at all levels: local, state, and federal. Collectively, groups of constituents (e.g., state associations) have substantial clout, especially if there is an established network of communication and committed members who have financial and other means of support. Large national associations, such as the APA, are perhaps the "wealthiest" politically because of the number of members nationwide who can give their support.

APA members, like members of other associations, can be involved in advocacy through grassroots activities which are quantitative and qualitative. Quantitative grassroots refers to the broad-based approach aimed at generating as many letters, calls, and visits to legislators as possible. Qualitative grassroots emphasizes the quality of the relationship (or the connection) between individual constituent and their legislators. These relationships require thoughtful interaction about common interests; communication that exists over time, not limited to meeting self-serving causes for either side; and meaningful contributions and responses one to another, that is, contributions that each side acknowledges and values. For legislators, constituents need to know that their concerns have been heard and met in the legislative process. For constituents, legislators look to them as a critical factor in political fundraising. It is a reality of American politics that funds are required to run for office or to be re-elected. Once again, members of the House of Representatives are particularly vulnerable because of their election schedule. For this reason, members of Congress appreciate financial support, regardless of the amount. Further, when there are a number of issues to which they might respond, they will choose those that are popular with their supporters. A clear sign of interest can be communicated through financial support. Thus, in spite of discussions to the contrary, until there is a significant change in the political process, a fact of life remains that constituents and organizations who can contribute funds will very likely have the most influence in the legislative process.

2.41.4.2 The Lobbyist

The lobbyist's three mottos are: (i) tell the truth; (ii) burn no bridges; and (iii) if you don't ask, you don't get (Wolpe, 1990). Lobbyists are conveyors of information. Helpful information is appreciated; information supporting and justifying an issue is essential for accomplishing one's advocacy objectives. Indeed, the main job of the lobbyist is to get decision makers interested and involved in the lobbyist's issues. Communications must be continuous, occurring on a regular and timely basis, through the use of newsletters, newspaper articles, internet, broadcast faxing, phone banks, and 800 numbers. Lobbyists must also educate and train their advocate participants about the process of advocacy: how the legislative process works, how to develop relationships with legislators, how to communicate with legislators, and the like. At APA this is accomplished by special training weekends with a group of psychologists around a particular target goal and culminating in visits. Ideally, in the future, this training will take place throughout the country on a state or regional basis so as to expand the number of psychology constituents/voters effective and knowledgeable about the advocacy process.

Lobbyists also need information themselves. Lobbyists need to know the field they represent, and the issues of their employers in order to be prepared to describe, explain, and justify issues and needs with legislators and their staff. For example, in the area of psychology and healthcare, lobbyists need to know the many ways the discipline contributes to good health, they must be able to answer complex questions, and be able to make the necessary connections between these contributions and the discipline's needs, say in the area of education and training. During each visit to legislators, it is imperative for the lobbyist to know just what they want to accomplish. They need to know the interests and idiosyncracies of their listeners in order to make their case, often during a time of high tension and great demands. Lobbyists, like constituents, need to establish relationships over a period of time, and preferably nurture these relationship during the quiet times afforded by Congressional recesses.

In addition, lobbyists must anticipate the opposition and solidify support from allies. Lobbyists need to be prepared to deal with the opposition, directly and indirectly. Most of all, they need the support of allies. In the political process, there is strength in numbers and relationships built over time on foundations of trust.

2.41.4.3 Third Parties: Organizations/Associations

Numbers count in the political process as a measure of interest and because they represent votes. Thus, an organization or association has a more powerful voice than an individual and a coalition of many organizations has significantly more power than just one organization. It is especially helpful when organizations can work together toward shared goals of mutual benefit. For this reason, whenever possible in advocacy efforts, organizations are sought with which to coordinate activities, complement and supplement efforts of one another. In some instances, membership in coalitions requires a fee to support paid staff to work on behalf of all the coalition members (e.g., Council on Education Funding). However, working with coalitions is a luxury not always available because of competing interests among groups with similar needs.

2.41.5 FUTURE DIRECTIONS

While the nature of advocacy seems straightforward, its implementation remains complex for the discipline of psychology. To be effective, the discipline must be accepted as a credible player in the legislative arena. People who have participated in national advocacy efforts are likely to have been surprised by the naivety about the discipline by well-meaning professionals in a variety of congressional offices and federal agencies. For example, there is often confusion of psychology with other mental health fields; a common question posed to psychology advocates is to explain how psychology differs from psychiatry, social work, or counseling. If psychology is not recognized as a discipline with important and unique contributions to make, then there is little incentive for policymakers and implementors to support its needs. Moreover, even when the discipline is recognized for its unique qualities in one area, for example, practice, it may be unknown for its potential to contribute to another area, for example, science. Because advocacy for psychology most often occurs within specific and limited interests rather than speaking to the discipline as a whole, the full range of the discipline often remains unknown and its real potential fragmented. For example, if taken as a whole, the discipline could be presented around a particular topic area (e.g., smoking cessation) in terms of the implications for education, research, and practice. In this way, each interest would serve to reinforce the others, the needs could be reinforced optimally and over the long term the message would find a meaningful context to the listener on a variety of issues. Yet, such an approach demands considerable coordination, assumes consistency of interests among psychologists, and requires a common understanding of and involvement in the advocacy process. None of these requirements is being met in the late 1990s. As a result, at best, federal policymakers have an uneven understanding of the field, its potential to contribute to the national good, and its many needs.

In a world of limited resources and a crowded political environment, advocacy is needed more than ever to garner the support of federal policymakers in order to establish psychology as a field of national significance of benefit to all Americans. To do this, all psychologists are needed to participate in the advocacy process. Internally, all psychologists must be educated about why advocacy is important to them and how to participate. Externally, education is needed to bring the benefits of the discipline to the public, to garner their support and, through them, the support of their representatives in Congress. To manage these efforts requires a central organization drawing together the breadth of the discipline. APA, the largest scientific and professional organization representing psychology in the United States, is positioned uniquely to play this role for the discipline. As the world's largest association of psychologists with a membership of over 150 000, the APA includes researchers, educators, clinicians, consultants, and students representing 51 different subfields of psychology and maintaining affiliation with all State Psychological Associations and territorial associations. With a mission to advance psychology as a science, as a profession, and as a means of promoting human welfare, the APA fits well as the focal point for advocacy in psychology. Organized according to the major interests of the discipline, Education, Practice, Public Interest, and Science, these structures also serve to direct its advocacy foci. Such an organization ensures attention to each interest group and its advocacy priorities. At the same time, separating these functions leads to challenging demands for the coordination of activities and priorities.

Given this organization, it is not surprising that the development of advocacy for the discipline mirrors the development of its separate parts. Thus, the more established areas like practice and science have the clearest messages and the greatest influence on the political process, both internally and externally. The newer and broader area of education is just beginning to establish its message to the discipline as well as in Congress. In an environment of relative wealth, these distinctions can work. Each interest group can focus on policy areas of greatest relevance to them, and work with those policymakers involved in their issues. As resources dwindle and the government seeks ways to limit its scope, these distinctions become troublesome; most often confusion develops around priorities.

In this way the discipline of psychology in the advocacy world suffers from its riches. The kind of direct message so central to good advocacy is not easy to achieve. Because it is a field with many subfields, a singular theme is often elusive. Because it is a discipline with at least four major interests: education, practice, public interest, and research, priorities can be difficult to establish. Education seeks to increase funds to educate and train current and future psychologists; Science works primarily with agencies to ensure that support is available for psychological research; so too Practice works most particularly on issues of parity for the psychologist practitioner; and Public Interest focuses on AIDS, Children and Families, Diversity, and like issues of public service. When legislation and policy parallels these as separate interests, work flows smoothly albeit without forcing what could be the benefit of contributions from the other interest areas. When the policy environment overlaps, for example, when the same Committee handles legislation related to two or more of these interests, separate messages can be confusing and the need to meet with the same members of Congress about different initiatives and priorities can appear as an uncoordinated strategy. Such confusion can be further exacerbated by the fact that different organizations, often with similar names, can arrive at the doorstep of the decision maker carrying different messages of needs and requests.

The next step for psychology advocacy is to be coordinated and complementary. The discipline of psychology can and will benefit from advocacy regardless of its focus. Advocacy priorities for the field need to be assessed by each interest group represented by the directorates in APA as well as the association as a whole. This process has begun, but like all collaborations, it takes time as each part learns to work with and trust the others. Further, this path of coordinated advocacy is challenged by the different levels of maturity and resources of each interest group. Whereas Practice advocacy has a long history of work, grass roots development, and active member involvement, Education is just beginning, has the fewest resources, and a constituent group (i.e., educators) largely unaware of the need of their involvement.

There is much to be done; there is enough work, and enough glory, for everyone to shine. There are great successes on which to build. Successful advocacy must be done by psychologists for psychology.

3.01.1 INTRODUCTION

Behavioral observation is a commonplace practice in our daily lives. As social creatures and "informal scientists," we rely upon observations of behavior to understand current social experiences and predict future social events. In fact, direct observation of behavior is one of the most important strategies we use to process our social world. Thus, it is not surprising that the field of psychology also is drawn to behavioral observation as a research method for understanding human behavior. The current chapter will focus upon behavioral observation as a formal research tool. In this context, behavioral observation involves the systematic observation of specific domains of behavior such that the resulting descriptions of behavior are replicable. In order to accomplish this task, the ongoing stream of behavior must be coded or broken down into recordable units, and the criteria for the assignment of labels or for making evaluations must be objectified. These practices of specifying units of behavior and objectifying coding criteria are the key steps in translating informal behavioral observations into formal, scientific observations. As will be seen below, the challenge of employing behavioral observation in research settings involves the myriad of decisions that an investigator must make in this translation process from informal to formal observation.

3.01.2 HISTORICAL INFLUENCES ON BEHAVIORAL OBSERVATION

The development of behavioral observation methodology is attributable to two major sources, the science of human behavior and the clinical practice of behaviorally oriented interventions. The science of human behavior is often traced to Watson and his colleagues (e.g., Watson & Raynor, 1924), who developed sophisticated methods to observe the behavior of children. Several important features distinguish this approach from early research that also used the observation of human actions as data. Most notably, unlike earlier trait-based researchers who measured behavior to make inferences about internal causes (e.g., Binet, Galton), the behavior itself is the focus of study. The approach also emphasizes direct observation in naturalistic settings as opposed to contrived responses that are elicited under artificial, controlled conditions. The further development of this approach was greatly stimulated by Skinner's (e.g., Skinner, 1938) theories that emphasized a focus on overt observable behavior, and by research manuals (e.g., Sidman, 1960) that further developed the rationale and methods for conducting and interpreting research on directly observed behaviors (Johnston & Pennypacker, 1993).

The second historical influence, behaviorally oriented clinical practice, also emphasizes direct observation under naturalistic circumstances. This approach defines pathology in terms of maladaptive behavior and then focuses on how environmental factors control maladaptive responding. Thus, behaviorally oriented clinicians conduct functional analyses to determine the environmental events that elicit and maintain maladaptive as opposed to adaptive behaviors, and they focus on observable behavior change as the criterion for treatment success. The need for precision both in measuring the behavior of interest and in identifying relevant environmental events has produced a body of scholarship on behavioral assessment as a clinical tool (e.g., Haynes, 1978; Hersen & Bellack, 1998), of which systematic behavioral observation is generally considered the hallmark strategy.

Ironically, Haynes (1998) notes that despite the theoretical importance of direct observation of behavior as a central feature of the behavioral approach, most research and clinical practice from a behaviorally oriented perspective relies on indirect measures such as self-report questionnaires. This increased reliance upon indirect assessment stems in part from the recognition that demonstrating improvement in subjective well-being is important, in addition to showing changes in overt behavior (e.g., Jacobson, 1985). Also, there has been an increasing emphasis on cognitions and other internal, nonobservable experiences (e.g., fear, dysphoria) as relevant focuses for behavioral intervention. However, Haynes suspects that most researchers and clinicians fail to conduct direct observations of relevant behaviors because they believe that the difficulty associated with conducting naturalistic observations outweighs the expected benefits in terms of incremental validity of the assessment.

Accordingly, recent advances in observational methodology and technology tend to come from fields of study and practice in which the veracity of self-reports is particularly suspect. For example, researchers and clinicians working with people who have mental retardation have produced important contributions in theory and methodology (e.g., Sackett, 1979b) as well as observational technology (Tapp & Walden, 1993). Similarly, research on infants and young children continues to emphasize direct observation over other types of measures (e.g., parent or teacher report).

Another more recent source for advances in behavioral observation is the growth of the marital and family systems perspective in clinical research and practice. This perspective emphasizes interpersonal exchanges as both focuses of interest in their own right and as contexts for individual functioning. The theoretical justification for this emphasis stems from family clinicians (e.g., Haley, 1971; Minuchin, 1974) who argue that couples, parent–child dyads, siblings, and larger family units are interacting subsystems that may cause and maintain pathological responding for individuals. In behavioral terms, marital and family interactions elicit and maintain maladaptive responding (e.g., Patterson, 1982). Because individuals are often biased reporters who have a limited perspective on the operation of the family system, observation of family interactions by outside observers is necessary for understanding these family processes. Thus, research and clinical work on marriage (e.g., Gottman, 1979), parenting (Patterson, 1982), and larger family units (e.g., Barton & Alexander, 1981) paved the way for many advances in observational technology and statistical approaches to analyzing observational data (e.g., Bakeman & Gottman, 1997).

3.01.3 THE PROS AND CONS OF BEHAVIORAL OBSERVATION

Behavioral observation is a fundamental form of measurement in clinical research and practice. The function of observation is the conversion of an ongoing, complex array of behavioral events into a complete and accurate set of data that can influence scientific or clinical decisions (Hawkins, 1979; Johnston & Pennypacker, 1993). As a measurement tool, behavioral observation is systematic; it is guided by a predetermined set of categories and criteria, and it is conducted by reliable observers (Bakeman & Gottman, 1997). In many instances, behavioral observation is the most objective form of measurement of relevant behaviors in relevant contexts because it is the most direct approach. Indeed, observations provide the yardstick against which other, more indirect measures, such as self-reports or rating scales, are evaluated.

In addition to providing direct, objective measurements, behavioral observation has several other strengths as an assessment tool. Hartmann and Wood (1990) note that (i) observation is flexible in providing various forms of data, such as counts of individual behaviors, or records of sequences of events; (ii) the measurements are relatively simple and noninferential, so that they are readily obtained by nonprofessional observers; and (iii) observations have a wide range of applicability across populations, behaviors, and settings. For clinical purposes, behavioral observation produces specificity in identifying problem behaviors that are targets for intervention, and in identifying causal and maintaining variables. Thus, it supports an idiographic, functional-analytic approach in which assessment leads to specific treatment goals. Furthermore, when observation is conducted in relevant settings, the data are criterion-referenced, so that treatment effects are likely to generalize to the natural environment.

Despite these strengths, behavioral observation also has several limitations. First, the "objectivity" of behavioral observation is far from absolute. Even when relatively simple forms of behavior are observed, the observational system imposes considerable structure on how behaviors are segmented and labeled which substantially affects the nature of the data that are obtained. Second, behavioral observation is expensive and labor-intensive as compared to self-reports. Third, observation cannot access inner experiences that are unobservable. Finally, observations provide only a limited snapshot of behavior under a specific set of circumstances, which often is not helpful for generalizing to other situations. Ironically, this latter limitation reveals how sensitivity to the effects of context on behavior is both a strength and limitation of this approach. Although behavioral observation is the method of choice for examining functional relationships that elicit and maintain actions in a particular context, such observations may have limited utility for predicting responses in different contexts or circumstances.

In designing a research study, an investigator has a variety of strategies available for gathering data, including self- and other-report measures, behavioral observation, and physiological indices, and must decide which and how many of these strategies are appropriate. Whereas behavioral observation may be more direct than self-report measures in many cases, observation is only a reasonable candidate if the investigator wishes to assess how an individual or group actually behaves in a given context. Understanding the different types of information that are obtained with each measurement strategy is critical when interpreting findings.

For example, in prevention studies to assist couples getting married, investigators often teach communication skills. Then, to assess whether the couples have learned these skills, they might employ behavioral observations of the couples' interactions, as well as obtaining self-report measures from the couples about their communication. In reviewing the findings across such investigations, an interesting pattern of results seems to have evolved. In most instances, investigators have been able to demonstrate that, based on behavioral observation, couples change the ways that they communicate with each other when asked to do so in a laboratory setting. However, on self-report measures, these same couples often report that their communication has not changed (Van Widenfelt, Baucom, & Gordon, 1997). How can we interpret these seemingly discrepant findings? Some investigators would argue that the behavioral observation findings are in some sense more meaningful because they reflect how the couple actually behaves. The self-report findings are more suspect because self-reports are subject to memory distortion, might reflect the couples' overall feelings about their marriages, and are impacted by response sets or test-taking attitudes. However, the results could be interpreted in other ways as well. Perhaps the couples' behavior in the laboratory does not reflect how they actually behave at home, and this discrepancy is demonstrated by the self-report data. Conversely, the behavioral observation in the laboratory might reflect ongoing behavior at home, but this behavior does not impact the couples' experience of their overall communication. That is, perhaps the intervention did not target, or the behavioral coding system did not capture, the critical elements of communication that impact the couples' subjective experience of how they communicate with each other.

When behavior is observed, the investigator must make a series of decisions that can significantly impact the results and interpretation of the findings. First, the investigator must decide what behavior to observe. This will include a consideration of (i) the setting in which the behavior will be observed, (ii) the length of time for observing the behavior on a given occasion, (iii) the number of occasions on which behavior will be observed, (iv) who will observe the behavior, and (v) the actual behavior that will be the focus of the investigation. After or while the data are gathered, it is coded according to some scheme or coding system. Thus, in evaluating a child's social behavior, the investigator must decide whether nonverbal facial cues will be coded, what verbal categories will be included in the coding system, whether the type of interaction such as play or classroom activities will be coded, and so forth. Once the behavior is coded, then the investigator must decide how to analyze the data. Often due to limited amounts of data or for conceptual reasons, specific codes are collapsed into larger codes; for example, many specific codes may be summarized as positive or negative behaviors. Finally, the investigator must decide how to analyze the data obtained from the observational coding scheme. Is the investigator interested in the frequency of various behaviors that were observed, or is the investigator focused upon the pattern of interaction and the interdependencies among various behaviors? These different questions of interest to the investigator will result in different data analytic strategies that will provide different information about the observed behavior.

3.01.4 OBTAINING OBSERVATIONS OF BEHAVIOR

The first challenge for an investigator who wishes to employ behavioral observation is deciding upon what behavior to observe, which actually involves a series of decisions. In almost all instances, the investigator is interested in drawing conclusions about a class of behaviors. However, the investigator can observe only a sample of that behavior while wishing to draw broader conclusions. For example, a family researcher might be interested in family interaction patterns and decide to observe a family while they interact around a dinner table; however, the investigator is interested in much more than dinner-time behavior. Similarly, a marital investigator might be interested in couples' communication fairly broadly, but observes their interaction for only 10 minutes in a laboratory setting. Or someone studying children's peer relationships might observe playground behavior at school but not in the neighborhood. In all of these instances, the investigator must be concerned with whether the sample of behavior is a representative or reasonable sample of the broader domain to which the investigator wishes to generalize.

3.01.4.1 Selection of a Setting for Observing Behavior

One major decision that the investigator must make is the setting for observing the behavior. A major distinction in this regard is whether the behavior is to be observed in a controlled or laboratory setting or in a more natural setting. Both strategies have their advantages and disadvantages. Laboratory settings have the asset of being more controlled, such that the behavior of various participants can be observed under more standard conditions. For example, a variety of parents and children can be brought into a laboratory setting and observed in the same setting with the same task. This standardized environment can be of help when interpreting the findings because it can help to exclude some alternative explanations of the findings based around differences among settings. For example, observing families in their home settings might be greatly impacted by whether there are interruptions from the outside, whether the home is excessively hot or cold, and so forth.

However, typically the investigator is interested in much more than laboratory behavior and wishes to draw conclusions about behavior in other settings in the natural environment. Not only are natural environments typically less controlled, but often the effort and expense involved in observing behavior in its natural environment is prohibitive. Therefore, in deciding which setting to employ in observing behavior, the investigator must address the question of the extent to which behavior observed in one setting is generalizable to other settings. Understandably, there is no general answer to this question, and it must be evaluated for the particular settings and participants of interest.

As an example of how this issue of generalizability of behavior across settings has been explored, Gottman (1979) evaluated couples' conversations both in a laboratory setting and at home. His findings indicated that although there is a tendency for couples to be more negative with each other at home than in a laboratory setting, along with more reciprocation of negative emotion at home, the couples generally demonstrated similar interaction patterns across settings. Even so, this finding applies only to the types of interaction that Gottman assessed with his particular sample, employing a given coding system. This issue of generalizability across settings from control/research settings to natural settings applies equally to generalizability within one of these domains, as is discussed later. For example, dinner-time behavior among family members in their own home might or might not reflect family interaction later in the evening when homework or bedtime activities are the focus of the family's discussion. Thus, even within a natural environment, behavior in one aspect of that setting might not reflect behavior in other aspects of the natural family environment. Consequently, the investigator should give a great deal of thought to the setting in which the behavior is observed in order to increase the likelihood that the resulting behavioral observations access the behavior of interest.

3.01.4.2 Selection of Live vs. Recorded Observation

The setting is altered by the experimenter when coders or recording devices are introduced into the environment. The decision to have coders present for the actual observation session, or instead to record the session for later coding, raises two major concerns. The first concern is the reactivity of live observation and recording equipment. Although research on this topic has a long history (e.g., Haynes & Horn, 1982; Kazdin, 1982), the findings are mixed and do not specifically address the relative effects on reactivity of having an observer present as opposed to using video or audio recording equipment. Much research shows that the presence of a live observer alters the behavior of subjects (Kazdin, 1982), and this reactivity may be greatest in intervention studies when the demands to display desired behaviors are relatively clear (e.g., Harris & Lahey, 1986). However, research on the reactivity of recording equipment is less certain. For example, studies using repeated sampling with recording equipment fail to detect habituation effects (e.g., Christensen & Hazzard, 1983; Pett, Wampold, Vaughn-Cole, & East, 1992), which suggests that the equipment does not evoke an initial orienting response. Further, studies that compare different recording methods show that relatively obtrusive as opposed to unobtrusive procedures produce few differences in the quality of most behaviors observed, although positivity may be increased somewhat (e.g., Carpenter & Merkel, 1988; Jacob, Tennenbaum, Seilhamer, Bargiel, & Sharon, 1994). Of course, it is possible that the mere presence of any type of recording equipment (or knowledge that it is present although unseen) may cause sustained changes in behavior similar to the effects of self-monitoring or participant observation (e.g., Jarrett & Nelson, 1984). Nevertheless, this set of studies suggests that using recording equipment with no observer present may be a relatively less reactive approach than live observation of behavior.

Another concern about live as opposed to recorded behavior is the accuracy of coded data. In general, we assume that video and audio recorded data help to improve coder accuracy because they provide the capacity to play back events repeatedly that are ambiguous or happen quickly. However, recorded data also may interfere with a coder's ability to attend selectively to salient behavior, particularly in a setting in which there is considerable background activity and noise. For example, Fagot and Hagen (1988) found that coders evaluating children in a preschool setting were less reliable and tended to miss relevant events when they coded from videotape as opposed to live observations. In part, the superiority of recorded observations depends on the ability to obtain excellent recordings. In many circumstances, audio recordings are particularly problematic because behavior is ambiguous without visual cues. When audio recordings are transcribed, some investigators also include live observers who make notes about nonverbal events that are added to the transcript.

3.01.4.3 Selection of a "Task" or Stimulus Conditions for Observing Behavior

Not only must investigators decide upon the physical setting for observing behavior, but the task or stimulus conditions within which the behavior is to be observed also must be decided. On many occasions, investigators ask the participants to engage in a specific task; on other occasions, the investigator merely decides to observe the participants' behavior in a given setting at a given time. If a particular task or interaction is structured by the investigator, then the effects of this particular task on the interaction must be considered. This is of less importance if the investigator is interested only in this particular type of interaction. For example, if an investigator is interested only in how a family would make weekend plans as a full family if asked to do so, then asking the full family to have such a discussion is relatively straightforward. However, the investigator might be interested in some more general question having to do with how the family makes decisions. If this is the issue of interest, then the investigator must carefully consider, and hopefully assess, the impact of this particular task involving planning a weekend. Deciding how to spend the weekend might or might not generalize to how the family makes decisions in other domains, such as how to divide household chores. Indeed, asking the family to sit and have a discussion resulting in weekend plans might not mirror how decisions are made in the family at all. Perhaps the parents make such decisions, or perhaps these decisions occur over the course of a number of informal interactions with different persons present at different times. More generally, when investigators structure particular types of interactions or ask the participants to engage in specific tasks, they must carefully consider whether the task or stimulus conditions that they have created mirror the ways in which the participants typically behave. Either the participants might behave differently when the task is different, or they might not typically engage in the task or situation that is constructed. The degree of concern raised by these issues is a function of the degree to which the investigator wishes to describe how the participants typically behave in their day-to-day lives.

How the task is selected also might impact the behavior. For example, Christensen and Heavey (1990) have described different interaction patterns among husbands and wives. This includes a well-known interaction pattern that they label "demand-withdraw," in which one partner presses for the discussion of a topic, and the other partner attempts to withdraw from the interaction. A number of investigations indicate that females are more likely to assume the "demand" role, and husbands are more likely to assume the "withdraw" role in marital interactions. However, Christensen and Heavey found that husbands were more likely to engage in the demand role during problem-solving interactions when the husbands selected the topic of conversation, compared to interactions in which the wife selected the topic to discuss. Thus, factors that influence an individual's interest in a task or motivation to participate in the task might significantly influence the resulting behavior that is observed.

3.01.4.4 Selection of a Time Period for Observing Behavior

In making decisions about the representativeness of the behavior that is observed, the investigator must also be concerned with the degree to which the observed behavior is generalizable across time. Classical test theory indicates that longer "tests" are more reliable in the sense that, keeping all other factors constant, they generally include a more representative sample of behavior and thus are more stable across time. In terms of behavioral observation, this raises two questions. First, how long should behavior be observed on a given occasion; second, on how many different occasions should behavior be observed? Whereas the answers to these questions should be based upon empirical findings, often pragmatic and logistic issues influence investigators' decisions along these lines. For example, sending observers into persons' homes or into classrooms can be troublesome and intrusive; sending observers to Africa to follow the social interactions among baboons can prove to be a logistical nightmare. Consequently, the difficulty, intrusiveness, and expense of behavioral observation often are a limiting factor in deciding how long to observe behavior. Similarly, the amount of time required to employ certain coding systems limits the length of behavioral observation. For example, some coding systems might require 20 hours to code one hour of recorded behavioral interaction. Therefore if the investigator intends to employ such a coding system, he or she might limit the amount of observed behavior to short time periods.

In deciding how long to observe behavior during a given observation period, several factors come into play. First and most generally, a long enough time period is needed such that the findings are relatively stable and replicable on other occasions. In part this is related to the frequency or base rate with which the behaviors of interest occur. If the behavior of interest is a relatively infrequent behavior, then longer observation periods are needed to obtain a stable assessment of its occurrence. However, if a behavior occurs with a high degree of frequency, then shorter observation periods can suffice. Second, the length of the observation period is influenced by the "complexity" of the phenomenon under consideration. For example, the investigator might be interested in whether there are different stages or phases in a couple's conversation as they attempt to reach resolution to a problem; in this instance, it would be essential to observe the entire problem-solving interaction. Or the investigator might be interested in whether there are different stages or phases in how a child responds to a new setting with the mother present. Attachment theory has explored this question and has provided indications of how securely and insecurely attached children initially respond in such settings, how they venture forth into a room after an initial exposure, and how their interaction with their mothers changes across time in this setting (Ainsworth, Blehar, Waters, & Wall, 1978). Therefore, if the investigator hypothesizes or wishes to explore whether there are different stages or phases in the interaction, this necessitates following the interaction for a sufficient time period to allow for an examination of the different phases of interest.

Second, the investigator must decide on how many occasions to observe the behavior. A given observation period might be significantly influenced by the occurrence of a major event, or the interaction of participants being observed might proceed in a given manner based upon what happens early in the interaction. For example, if a child is taunted on the playground early during a recess period, the child might withdraw from the group, which will significantly impact the child's behavior for the duration of the observation period on the playground. If the child is not taunted the next day, then his or her interaction pattern might proceed quite differently. Consequently, the number of occasions on which to observe interaction will differ according to the variability in the behavior being observed. If the behavior of interest occurs in a relatively consistent manner across different occasions, then fewer occasions are necessary for obtaining a stable sample of behavior.

Whereas there are far too few empirical investigations that have been conducted to determine the number of observational sessions needed to obtain stable results, some such investigations do exist. For example, Wieder and Weiss (1980) explored how many observational sessions were needed in order to obtain a stable assessment of couples' interaction when employing the Marital Interaction Coding System (MICS; Weiss, 1986). Based on generalizability theory, they concluded that observing couples on a single occasion could provide meaningful information about the couple, but observations across two separate evenings provide more stable interactions patterns when coded by the MICS. Similarly, Haynes, Follingstad, and Sullivan (1979) found that across three evenings, there was high stability on only 5 of 10 selected coding categories of communication between spouses. Interestingly, in spite of these findings, no marital therapy outcome investigations have observed couples' interactions across two or more consecutive evenings.

As can be seen based on the above discussion, there are a number of questions that the investigator must address in deciding what behaviors to observe. The decisions that are made will certainly impact the investigator's findings. Yet before these findings are obtained, there are many more decisions for the investigator to make that will influence the results.

3.01.5 ADOPTING OR DEVELOPING A BEHAVIORAL CODING SYSTEM

Foremost among the additional decisions to be made is the choice of coding system to employ to classify the data that have been observed. In fact, in order to address the questions raised above regarding what behavior to assess, the investigator needs to know ahead of time what coding system he or she will employ. At times the behavior is coded live during the interaction, so the coding system must be known. Even if the observed behavior is to be coded later based on video recordings of the behavior, it is important to decide ahead of time what coding system will be employed. For example, some coding systems might be appropriate only in certain settings or with certain tasks. Similarly, some coding systems might break behavior into a number of fine-grained categories that occur on a somewhat infrequent basis, thus necessitating longer observational periods. Therefore, deciding what coding system to employ is a significant factor in developing a thoughtful study based on behavioral observation.

An initial consideration in selecting a coding system is whether to adopt an existing coding system or to develop a new one. Each approach has some obvious benefits and limitations, as well as other subtle impacts that may not be apparent to investigators until they are well into the task of coding the behavioral observations.

3.01.5.1 Adopting an Existing Coding System

In many cases, it may be possible to adopt a coding system that has been used previously in the same research area, or one that can be imported from another area where similar constructs were assessed. Adoption of an existing system has the great advantage of saving the time and energy required to develop a reliable, valid, and practical coding scheme. It also links research across laboratories, samples, and locations, and thus provides for ready synthesis of research findings from various studies.

The selection of a coding system is guided by both theoretical and practical considerations. The primary theoretical issue is whether the coding system assesses behaviors that address the constructs of interest to the investigator. All coding systems organize data into some set of categories or units for coding, and these categories are based on issues of importance to the person who developed the coding system; however, they might or might not coincide with another investigator's concerns or theoretical model. Before beginning a search for a coding system, it is essential that the investigator first review theory and research to clarify the nature of the behavioral phenomena under investigation.

Behavioral phenomena related to a construct under one situation may take on different characteristics in a new situation, thus making an existing system inappropriate. For example, Ammerman, Van Hasselt, and Hersen (1991) coded problem-solving interactions between children with visual impairments and their parents using the Marital Interaction Coding System, III (MICS III; Weiss, 1986), a well-validated system for assessing problem-solving interactions within marital dyads. The study detected no differences between groups of families with and without children with disabilities, possibly because the coding system was inappropriate for the family context. Whereas the MICS III evaluates warm and hostile exchanges that indeed were similar across the groups, it does not assess factors such as behavior management, instruction, or other socialization practices that are important aspects of parent–child exchanges that are responsive to children's disabilities (Floyd & Costigan, 1997). Thus, a behavioral coding system may be sensitive to relevant variables only for certain types of people, relationships, or circumstances.

In addition to the substantive content of the system, various coding systems differ in the ways that they "chunk" or segment behavior into coding units. This "chunking" of behavior has both theoretical and practical implications for investigators. From a theoretical perspective, the nature of the phenomena being assessed should influence how the stream of ongoing behavior is segmented (Floyd, 1989). More specifically, relatively small, elemental units of analysis may be appropriate for evaluating discrete events that require little inference; however, larger units of behavior might be needed to capture more complex phenomena. Foster, Inderbitzen, and Nangle (1993) discuss a similar point regarding the selection of a coding system to evaluate the effectiveness of social skills training with children. They note that a frequent problem with interpreting the results of treatment outcome studies is that whereas the treatment teaches children specific social skills, such as offering to share a toy, the observational assessment evaluates only molar, or global codes, such as "positive interactions." From data such as these, it is impossible to know whether the behaviors that were trained actually were displayed during the assessment.

Alternatively, it also is important to question whether a complex phenomenon is accurately evaluated by merely summarizing elemental codes. For example, Jacob (1975) illustrates how power in interpersonal interactions may not be indicated by who speaks more frequently or wins more disagreements, but rather by the ability to prevail on the central, important conflicts. Evaluations such as these may require making judgments about relatively large units of behavior.

Choosing among systems with different units of observation also has practical implications. Microanalytic coding systems that parse behaviors into minute elements may be overly complex and labor-intensive for investigators who merely want to assess global levels of characteristics, such as positiveness, competence, anxiety, or irritability. In such cases, it may be more efficient to use a system that rates dimensions such as the intensity or quality of behavior exhibited over an extended period of time. On the other hand, small, elemental units of observation and analysis are useful for detecting situational influences on behavior and sequential patterns among minute events; larger, more integrative units are useful for understanding cross-situational consistency (Cairns & Green, 1979). Thus, findings based on larger units of observation may be more generalizable than microanalytic coding. Some investigators appear to assume that behavioral observation is synonymous with microanalytic coding; such assumptions can serve as a major impediment to the more widespread use of observational measures in research settings with limited resources. We encourage investigators to explore macroanalytical coding procedures as a practical and, in some cases, more informative alternative to microanalytic coding.

Every coding system incorporates an array of assumptions, biases, and procedural preferences that the originator used to guide coding decisions. These preferences are particularly relevant in decisions about how to handle ambiguous incidents. Many decision rules are not made explicit in published reports and coding manuals, so that it is difficult for investigators who did not participate in its development to apply an existing system accurately and in a way that is consistent with other research. Whenever possible, consultation with the originator is invaluable. Some originators of popular measures conduct periodic workshops to train new users (e.g., SASB, Humphrey & Benjamin 1989; SPAFF, Gottman, 1994). Most developers cannot be expected to provide ongoing consultation to support their system, but should be willing to share examples of coded data and advice about common problems.

3.01.5.2 Developing a New Coding System

New ideas focused on new constructs and employing new assumptions are the lifeblood of progress in the social sciences. Thus, there will always be a need to develop new coding schemes. Even when well-known constructs are studied, if observational procedures become highly standardized within a research area, the phenomenon of interest may become totally dependent on the existing measure. This situation can lead to replicated, well-established findings that are largely an artifact of a particular measurement procedure. The need to disentangle method variance from the phenomenon of interest is strong justification for the development of new coding systems.

Detailed instructions about developing coding systems are given in Bakeman & Gottman (1997) regarding interpersonal interaction, and by O'Neill, Horner, Albin, Storey, and Sprague (1990) regarding functional analysis of problem behaviors. The key steps in developing any coding system are summarized below.

3.01.5.2.1 Cataloging relevant behaviors

A useful initial step is to develop an exhaustive list of all relevant behaviors to be coded. In some cases, this may be accomplished by conducting initial observations and recording all relevant behaviors that occur. Animal researchers frequently use this procedure to develop an ethogram, which is a comprehensive list of all behaviors that are characteristic of a species. Several ethograms are published to describe the behavior repertoire of different animal species. However, because it is usually impossible to sample all possible behaviors for a species, investigators estimate the quality of sample coverage with the theta statistic, calculated as 1 – (number of different behaviors seen/total number of acts observed). As the value of theta approaches 1, the probability of encountering a new behavior approaches zero. That is, we assume that if new behaviors are not encountered with additional observations, the behavioral repertoire has been adequately sampled.

Of course, a strictly empirical approach such as this usually is not adequate for evaluating human behavior. As we noted at the beginning of the chapter, a stream of human behavior often can be classified according to an enormous variety of characteristics. In order to focus attention on a limited set of characteristics, the investigator should begin with a list of these characteristics and their manifestations as gleaned from previous research, experience, and theory. Pilot observations then can be directed toward refining this list by broadening some categories, tightening others to make finer distinctions between theoretically disparate behaviors, and adding new categories not suggested by previous research. For an excellent example of this process, see Jacob, Tennenbaum, Bargiel and Seilhamer's (1995) description of the development of their Home Interaction Scoring System.

One frequent concern while developing coding systems involves what to do with rare but theoretically important events. Rare events tend to decrease the reliability of coding systems; however, such rare events may be highly meaningful, and thus they cannot be excluded from a system without compromising validity and utility. It may be possible to collapse similar rare events into broader categories or to alter the observational situation in order to elicit these behaviors more consistently and reliably.

3.01.5.2.2 Selecting a unit of observation

An important component of identifying relevant behaviors is to determine the appropriate unit of observation. This involves the decision to evaluate behavioral states, events, or some combination of the two. In general, a state is any ongoing condition that persists over an extended period of time, whereas an event is a discrete action. States are usually measured with time-based indices such as duration or latency, whereas events are usually measured with frequency counts or sequential patterns. Both types of unit also can be rated for intensity. The distinction between states and events is blurred by the fact that the same behavior might be measured with both units, such as measuring both the duration of anxiety episodes or disruptive episodes in the classroom, as well as the frequency of the episodes. The type of unit is not always mandated by the content of the behavior and, once again, the decision about the appropriate unit for a particular purpose must be guided by theoretical, empirical, and practical considerations. At first glance, it may appear that recording onset and offset times for all behaviors is desirable so that information about duration and latency can always be retrieved. However, Bakeman and Gottman (1997) warn against "the tyranny of time" and propose that, even with sophisticated recording and analytical devices, the precise measurement of time adds substantial complexity to data recording and analysis, and can cause problems with reliability that outweigh the benefits of having these data.

The unit of observation also involves the sampling protocol. The two most common sampling protocols in clinical psychology research are event sampling, which involves noting each occurrence of events during the entire observation period, and time sampling or interval coding, which involves noting occurrences during selected time intervals. Most commonly, time sampling involves alternating periods of watching and recording, each lasting for several seconds. During the recording period, the coder usually records whether or not each possible code occurred during the preceding interval. This procedure is useful for live observations in which the coder must track a large number of behaviors, so that recording each event would interfere with accurate observation. The procedure assumes that recording periods are random, and will not distort the data. Several studies challenge this assumption and reveal that interval coding can distort the amount of behavior, sequential patterns, and observer agreement for both behavioral events (e.g., Mehm & Knutson, 1987) and behavioral states (e.g., Ary, 1984; Gardner & Griffin, 1989). However, other studies demonstrate that interval coding can accurately reflect actual behavior rates and durations (e.g., Klesges, Woolfrey, & Vollmer, 1985). A study by Mann, ten-Have, Plunkett, and Meisels (1991) on mother–infant interactions illustrates that the accuracy of data from interval sampling depends on how well the duration of the sampling interval matches with the duration of the behavior of interest. They found that the actual durations or frequencies of mother and infant behaviors, which tended to occur in relatively short episodes ("bouts"), were inaccurately assessed when the sampling interval was relatively long. Thus, before proceeding with a time-sampling/interval-coding approach, the investigator should test the time-sampled data against actual rates or durations, and adjust the length of the recording interval to produce the most accurate data possible. See Altmann (1974) for an extensive review of sampling protocols, and Bakeman and Quera (1995) for considerations about how to design sampling protocols and record the data for data analysis purposes.

3.01.5.2.3 Creating code categories

Typically, code categories will be mutually exclusive and exhaustive Mutual exclusivity means that coding categories are discrete and homogeneous, and that each event can be classified into one and only one category. Exhaustiveness means that all manifestations of a construct are included in the system. In most cases, exhaustiveness can be achieved by including a category, such as "other" or "neutral," to label all behaviors that do not fit well into any other category. For example, a measure of parent–adolescent interaction by Robin and Foster (1989) includes a "talk" code to cover all behaviors that are not instances of other categories. In some cases, the investigator may believe that it is necessary to violate these guidelines. For example, another measure of parent–adolescent interaction, the Constraining and Enabling Coding System (Leaper et al., 1989), allows behaviors by parents to receive both "constraining" and "enabling" codes because the authors believe that these "mixed messages" may be highly relevant to adolescent functioning. In other cases, investigators only label certain subsets of behaviors (i.e., as in scan sampling where, for example, only instances of target children's aggressive behavior and provocations by peers are recorded). Both situations create difficulties for the analysis of sequences of events, although Bakeman and Quera (1995) provide some solutions for managing these types of data.

Often it is useful to organize codes into groups and, if appropriate, to arrange the groups into a hierarchical classification. This arrangement makes the codes easier to recall; in addition, this hierarchical arrangement can help to fashion a set of decision steps to employ in the coding process, both of which may improve observer reliability. For example, children's social behaviors might first be classified as initiations versus reactions, and initiations could be classified as prosocial versus antagonistic, followed by more specific categories of events within each of these general categories. The coders can then use this hierarchical arrangement to organize their decision process, so that once they decide that a particular action is an initiation, and it is prosocial, there is a relatively small number of "prosocial initiation" codes to choose among.

An alternative approach to forming a hierarchical organization is exemplified in the Structural Analysis of Social Behavior (SASB) system (Humphrey & Benjamin, 1989). This system uses a rating scale format as an aid to categorical coding. In this system, all code categories are classified within a circumplex defined by two dimensions: Interdependence and Affiliation. Coders receive extensive instruction in the theory underlying each dimension, and they learn to rate behaviors in terms of their degree of interdependence, represented on a vertical axis, and their degree of affiliation, represented on a horizontal axis. The axes intersect at their midpoints. The location on the circumplex defined by the coordinates of these dimensional ratings is the code for that act. Thus, for example, a behavior rated as +5 for Interdependence (i.e., somewhat independent) and −4 for Affiliation (i.e., somewhat disaffiliative) is assigned to the category "walling off and distancing."

3.01.5.2.4 *Content validation of codes*

A useful, though often neglected, step in coding system development is content validation of the codes. This might be accomplished by having "experts" or the actors themselves classify codes into relevant categories, then comparing these categories to the expected categories. For example, in order to evaluate a family coding system that classified family behaviors as aversive and nonaversive, Snyder (1983) had family members rate the aversiveness of concrete examples of behaviors classified by the coding system.

3.01.5.2.5 *Developing a codebook*

After codes are labeled, defined, and classified, the next step is to produce a codebook. In general, most experts recommend that the more thorough, precise, and clearly written the codebook, the better the chances of training new coders to produce reliable, valid data (e.g., Hartmann & Wood, 1990; Herbert & Attridge, 1975); however, other studies demonstrate that naive coders can at times produce valid codes (e.g., Prinz & Kent, 1978). The codebook should include a list of all codes, a descriptive definition for each code, and examples of behaviors that represent each code, along with examples that do not match the code. In order to assist with reliable coding, it is particularly important to include examples of differential decisions in borderline or ambiguous cases. The APA guidelines for educational and psychological tests (APA, 1985) lists several other types of information that would also be useful to include in codebooks, including information about the theoretical underpinnings for the measure, and data on reliability and validity from research to date. Herbert and Attridge (1975) propose that providing this type of information to coders may help to facilitate training and improve coder reliability.

3.01.6 TRAINING CODERS

Once a coding system has been adopted or developed, the next step is to train coders in its use. A preliminary step in conducting efficient and effective coder training is the selection of coders who will perform well. Unfortunately, there is little research on personal characteristics or abilities that predict good performance as a behavioral coder. Research on interpersonal communication indicates that, in some circumstances, women tend to be more accurate than men at decoding the meaning of interpersonal behaviors (e.g., Noller, 1980). However, this effect is hardly large enough to warrant the exclusion of male coders in studies of interpersonal behavior. To the extent that coder characteristics such as gender, age, education, or ethnicity may be associated with biases that could influence coding decisions, it may be important to ensure that coders are diverse on these characteristics in order to randomize these effects and improve the validity of the data.

Ironically, one characteristic that may be important to select *against* is prior experience or personal investment in the research area under consideration. The use of naive, uninvolved observers controls for biases caused by factors such as familiarity with the research hypotheses and prior expectations. We believe that in many instances naive observers also tend to provide more reliable codes. Extensive research on clinical decision making demonstrates that highly experienced judges tend to employ idiosyncratic and inconsistent decision criteria that can reduce both intraobserver consistency and interobserver agreement as compared to naive observers (e.g., Dawes, 1979). Our experiences bear this out. When coders have extensive previous training or experience in the domain of interest, they tend to have difficulty adhering strictly to the coding criteria outlined in the coding manual, particularly if their experiences involved a different theoretical perspective or set of assumptions than those that undergird the coding system.

Wilson (1982) wisely proposed that observer training should address two equally important goals: teaching the skills needed to perform the coding task, and motivating the coders to perform well. Teaching the skills usually involves a combination of didactic and experiential training sessions. A helpful first step is to explain the rationale and theory that underlie the coding system. In cases where the coding involves considerable judgment in the application of a theory or model, the coders might benefit from readings and instruction about the model. The coders should read and demonstrate a thorough working knowledge of the coding manual and should be tested on this material before proceeding. Practice with the coding system should begin with the presentation of examples of behaviors, followed by an explanation for the coding decisions. Initial examples should be relatively unambiguous representations of the coding categories or examples of the extremes of the rating scales. The coders should be required to practice the coding with feedback about their accuracy and discussion of the rationale for coding decisions. Of course, the practice materials should match the actual coding situation as closely as possible. Training sessions should be relatively frequent and relatively brief to enhance alertness. Training continues until the coders reach acceptable levels of agreement with preestablished criterion codes. Because accuracy can be expected to decrease once actual coding begins (e.g., Taplin & Reid, 1973), most investigators set a training criterion that is higher than the minimal acceptable criterion during actual coding. Typically, this criterion is 80–90% agreement.

The maintenance of the coders' motivation to perform well probably involves the same types of factors that enhance performance in any work setting, including clarity of the task, investment in the outcome, personal responsibility, monitoring of performance, and a fair reward structure. One typical procedure used by investigators is to develop a contract that specifies the tasks to be completed, the expectations, and the reward structure. Coder investment in the project might be enhanced by providing them with the opportunity to participate as a member of the scientific or clinical team, to the extent that this does not bias coding, or by group interactions that build solidarity and cohesion among the coding team. As described below, reliability should be monitored on an ongoing basis. An unfortunate feature of reliability monitoring is that there is a built-in punishment schedule for inadequate performance, such as having to recode sessions or completing additional training, but the rewards for good performance are less tangible. Investigators should be sensitive to the need to instigate a reward system in whatever way possible, including providing raises for a good record, greater responsibility in the form of training and monitoring new coders, or public acknowledgment of good work.

3.01.7 RELIABILITY

In observational research, the reliability, or precision, of the measure is almost always evaluated with indices of interobserver agreement. Actually, according to psychometric theory, reliability concerns the extent to which coded data map onto "true scores," and thus, the reliability of coded data also relates to intraobserver consistency in applying the coding scheme (Bakeman & Gottman, 1997). However, because agreement between independent coders is a higher standard for judging precision, it is the focus of formal psychometric evaluations, and intraobserver consistency is addressed more informally through the implementation of training and monitoring procedures to prevent observer drift.

3.01.7.1 Enhancing Reliability

As noted throughout the previous sections, reliability can be enhanced in the way the codes are developed, in the procedures for training and monitoring the observers, and in the procedures for conducting the observations. Regarding code development, greater reliability can be expected when codes are clearly defined in operational terms, when categories are relatively elemental and overt as opposed to complex and inferential, and when coded behaviors occur at least moderately frequently. If some of these conditions cannot be met, coders likely will need relatively more training, practice, and experience in order to produce reliable data. Instructions that explicitly discourage or encourage specific expectancies about frequencies or patterns of codes either tend to reduce observer agreement or spuriously inflate it (Kazdin, 1977). Similar to guidelines for training sessions, frequent and relatively short observation sessions produce more reliable data than infrequent, longer observation sessions. In addition to booster sessions to reduce observer drift, periodically training new coders may help to reduce the biasing effects of prior experience on the data, and observations involving different subject groups or experimental conditions should be intermingled whenever possible to avoid systematic effects related to observer drift. Studies repeatedly demonstrate that coders are less reliable when they believe that their agreement is not being checked, although this effect may abate with increased experience (e.g., Serbin, Citron, &

Conner, 1978; Weinrott & Jones, 1984). Therefore, frequent, overt, and random assessments of reliability should help to maintain coder precision.

3.01.7.2 Evaluating Reliability

The appropriate procedure and calculations for evaluating reliability depend on the purposes of the evaluation and the nature of the inferences that will be drawn from the data. Thus, there is no one way to evaluate reliability, but rather an array of approaches that can be followed. Helpful reviews of various procedures and computational formulas are presented by Bakeman and Gottman (1997), Hartmann (1977, 1982), Jacob, Tennenbaum, and Krahn (1987), Stine (1989), and Suen, Ary, and Covalt (1990). Two important decisions include (i) whether to compute exact agreement for specific codes (point-by-point agreement) or aggregate agreement for larger units, and (ii) whether and how to correct for chance agreement. Below is a summary of some of the more common procedures, along with guidelines for selecting among them.

For the purpose of training, monitoring, and providing corrective feedback to coders, in most cases it is useful to assess the most precise form of point-by-piont agreement that is possible with the coding system. For example, with event recording, an observer's codes for each event are compared with a set of criterion codes or those of an independent coder. A contingency table that cross-lists the two sets of codes and tallies the frequencies of each pair of codes (i.e., a "confusion matrix") is a useful method of feedback for the coders. The total percent agreement for all codes (# agreements/total # events), and the percent agreement for specific codes (# agreements/(#agreements + #disagreements)) are summary scores that are easy to understand. During coder training, we compute these statistics beginning with the first practice assignments because the rapid improvement that usually occurs during the first few assignments can be highly rewarding and reinforcing for new coders. The contingency table also can display a pattern of disagreements that is instructive, such as when two coders consistently give a different code to the same type of behavior. Even when the actual observational procedure involves a larger or less precise unit of observation, such as in interval sampling, it may be helpful to employ an event-based tracking procedure during coder training in order to have more precise information about when disagreements occur. In our experience, the identification of consistent disagreements is helpful when follow-up instruction is used to clarify and resolve the confusion about the coding criteria. However, providing feedback about disagreements without instruction or resolution can make coders feel more confused and uncertain and can decrease reliability. Also, it usually is not helpful to coders to correct their scores for chance agreement, because corrected scores may be highly variable depending on the range of behaviors displayed in each session; thus they present a confusing picture of absolute agreement. Finally, if agreement statistics are used to identify unreliable coders in need of additional training, it is important to base this decision on multiple observation sessions, because occasional unreliable sessions can be expected due to the ambiguity in the target's behavior rather than because of coder error.

For the purpose of determining the precision of the measurement after coding has been completed, the method of computing reliability depends on the type of data that will be analyzed (Hartmann, 1977). That is, the investigator typically is interested in the reliability/precision of the scores that are actually computed from the data. Although it is common for investigators to report some form of point-by-point agreement for individual codes, most data analyses focus on aggregate indices such as the frequency, relative frequency, or rates of groups of behaviors. Thus, if several specific codes are combined or aggregated into a broader category of "positive behavior" for data-analytic purposes, then reliability estimates should be performed at the level of "positive behavior." We usually assume that observer agreement for specific codes ensures that aggregate scores are reliable; nonetheless, it is useful to determine the actual level of reliability for these aggregate codes. Furthermore, agreement at the specific code level is usually an overly stringent requirement that can unnecessarily prolong a study.

For the purpose of assessing the precision of the measure, percent agreement statistics are usually corrected for chance agreement between coders by using Cohen's kappa statistic. This statistic uses the information about agreements and disagreements from the confusion matrix, and evaluates the observed amount of agreement relative to the expected amount of agreement due to chance because of the base rates of the behaviors. The formula for kappa is: kappa = [p(Observed agreement) $-$ p(Expected agreement)]/[1 $-$ p(Expected agreement)], where p(Observed agreement) is the percent agreement for the two coders, and p(Expected agreement) is the percent agreement expected by chance. The probability of chance agreement is computed by calculating the relative frequencies for each code by each coder, obtaining the product of the two coders' relative frequency scores for each code, then summing these products. Usually, kappa is computed for each reliability session, and the mean and range across all reliability sessions are reported. One complication with the kappa statistic is that it can severely underrepresent observer agreement in sessions during which the subject displays a limited number of behaviors and/or some behaviors have exceptionally high base rates. This situation produces very large values for expected agreement, and thus can produce a very low score for kappa even when the proportion of observed agreement is very high. A potential solution in this situation is to use a sample-wise estimate of expected agreement derived from the base rates for the entire set of data (Bakeman & Gottman, 1997). Another complication is that point-by-point kappa may be overly stringent when, as frequently occurs, the actual scores used in the data analysis are aggregates (e.g., total frequency scores). Jacob et al. (1987) present a method for computing kappa for aggregate scores.

Often the measure of interest in the data analysis represents the data on an interval scale of measurement (e.g., relative frequency scores or average ratings). In this situation, the question of measurement precision concerns the relative positions of subjects on the interval scale rather than agreement between coders on individual coded behaviors. Coder agreement for interval data can be assessed with the correlation between the scores for pairs of coders; for example, the correlation between summary scores for a group of subjects, or the correlation between interval ratings within an observation session. Alternatively, the intraclass correlation is also appropriate for interval data. This approach is derived from the analysis of variance (Winer, 1971), and is the most commonly used application of generalizability theory for evaluating coder agreement. It assesses the proportion of variance in the scores that can be attributed to variation among subjects as opposed to variation among observers. An advantage of the approach is that when more than two coders are being evaluated, one score can reflect the level of agreement (i.e., proportion of variation attributed to differences among subjects) for the entire group of coders, rather than calculating individual correlations for all possible pairs of coders. Shrout and Fleiss (1979) outline the procedures for computing intraclass correlations under various assumptions about the data.

Alternative procedures for detecting agreement between coders may also be appropriate when the focus of study is the sequential patterns in the behavioral stream. Bakeman and Gottman (1997) vividly illustrate how point-by-point agreement between coders can be sharply deflated when one coder occasionally inserts extra codes, although the agreement about the sequential pattern of the codes is very high. Wampold and Holloway (1983) make a similar case that agreement about individual codes may be too stringent a criterion for sequential data. Gottman (1980) recommends an approach similar to intraclass correlation in which the investigator demonstrates that the measures of sequential dependency (e.g., lag z-scores, see below) are consistent across observers.

3.01.8 ANALYZING DATA GATHERED THROUGH BEHAVIORAL OBSERVATION

Apart from the usual decisions that guide the design of data analysis, observational data present some unique challenges for investigators. These include questions about data reduction, dimensions and scales of measurement, and the identification of sequential patterns of behavior.

3.01.8.1 Data Reduction

Most observational studies produce a large amount of data for each subject, particularly when the coding scheme exhaustively labels all behaviors emitted by one or more subjects during an observational session. Even sessions lasting only 5–10 minutes can produce several hundred codes when behavior units are small. The challenge is to reduce these data to make them interpretable, without sacrificing the rich descriptive information in the coded data.

A first step is to group individual codes into broader categories. For the purposes of data analysis, the primary problem with many observational coding schemes is that they include behavioral events that rarely or never occur for many subjects, and thus produce highly skewed distributions of scores for the sample, resulting in missing cells in contingency tables for sequential analyses. Whenever possible, it is important to incorporate rare events into categories of events that occur with sufficient frequency to be used in subsequent analyses. In most cases, categories are specified on an *a priori* basis by investigators, using theory and rational analysis to determine how codes are grouped.

Another approach is to factor analyze individual codes to identify clusters of codes that share common variance. This approach is probably most appropriate when the investigator is interested in examining behavior styles, because the factor analysis identifies groups of behaviors that covary across subjects. That is, behaviors are grouped based on their co-occurrence within subjects, irrespective of their meaning or functional impact. For example, if different children in classrooms tend to misbehave in different ways, with some children spending much time out of their seats, others talking out of turn, and others being withdrawn and inattentive, a factor analysis would likely identify these three types of behaviors as three separate clusters. Kuller and Linsten (1992) used this method and identified social behaviors and individual concentration as separate clusters of behaviors by children in classrooms. An alternative approach is to group behaviors according to their functional impact. If all three types of behaviors disrupt the activities of other children in the classroom, they can be grouped into one functional category of disruptive behavior. For example, Schaap (1982) used lag sequential analysis of marital interactions to identify a set of behaviors that were most likely to elicit negative responses from a spouse. These specific behaviors could then be grouped together as negative eliciting behaviors.

3.01.8.1.1 Measurement of base rates of behavior

Base rates of behavior can be expressed in various scales of measurement. For example, the frequency of events can be expressed as raw frequency, relative frequency, rate per minute, or ratio scores (i.e., ratio of positive to negative behaviors). The selection of a scale of measurement is usually determined by factors such as the focus of the investigation, the precedent in the field of study, and psychometric properties of various scales of measurement (e.g., distributions of the scores, reliability of the index). Tryon (1991) argues that scores should also be expressed in "natural" scientific units in order to make measurements as comparable as possible across time, situations, or different investigations. A compelling point in this argument is that relativistic measurements such as standardized *z*-scores, which provide information about the position of the subject relative to other subjects in the same study, are highly "unnatural" units that vary as a function of who participates in the study. Instead, scores should be expressed in relation to some objective criterion that remains invariant across samples, so that a body of knowledge about the phenomenon of interest can more readily develop. For example, because raw frequency counts will depend on the duration of the measurement period, relative frequency scores may be preferable because they are comparable across measurement situations. However, the comparability of relative frequency scores requires exhaustive coding of all behavior with the same set of codes. Thus, rate per minute scores may be preferable because they are less dependent on other characteristics of the coding scheme or measurement situation.

3.01.8.1.2 Measurement of sequential patterns of behavior

When events or states are coded exhaustively, it is possible to evaluate patterns of behavior for an individual or between individuals interacting with each other. The behaviors can occur concurrently (e.g., the co-occurrence of eyebrow arch and smile) or serially (e.g., reciprocal negative behaviors between spouses). Sequential patterns are usually derived from Bayesian statistics that relate the occurrence or nonoccurrence of an antecedent event or state with the occurrence or nonoccurrence of a consequent event or state. In lag-sequential analysis (e.g., Bakeman & Gottman, 1997; Sackett, 1979a), the investigator is concerned with the transitional probability of the antecedent/consequent sequence, which reveals the probability that the consequent occurs, given the antecedent event or state. The important question regarding sequential dependency is the extent to which this transitional probability exceeds (or is smaller than) the base rate for the consequent. If the consequent is more (or less) likely to occur in the presence of, or following, the antecedent than in other circumstances, then there is dependency between the antecedent and the consequent. If, for example, the probability that a mother smiles at her infant (consequent behavior) is greater after the infant smiles at her (antecedent behavior) than after other types of infant behaviors, then there is a sequential dependency in infant smile–mother smile exchanges.

Sequential dependency can be estimated with several statistics. One common metric is the lag sequential *z*-score developed by Sackett (1979a), and a modification developed by Allison and Liker (1982) that corrects for sampling error. This statistic compares the observed frequency of the antecedent/consequent sequence with the expected frequency of the sequence (based on the base rates for both events). More recently, Bakeman and colleagues (Bakeman & Gottman, 1997; Bakeman & Quera, 1995) recommended a slightly different formula derived from two-way contingency tables, which is the adjusted residual obtained in log-linear analysis. A convenient feature of this statistic is that because the scores are distributed as z, the statistical significance of sequential patterns is readily discerned (i.e., scores greater than $z = 1.96$). The statistic can be computed with standard statistical packages. Importantly, Bakeman and Quera (1995) also suggest statistical programs to compute these scores when codes in a sequence cannot repeat, such as when the coding system requires that new codes are assigned only when the behavior changes. Because a behavior can never follow itself, this situation produces "structural zeros" in the diagonal of the contingency table.

The z-statistic or adjusted residual is most useful for examining a sequential pattern in a single set of observations on an individual subject or a group of subjects. However, it is not recommended for use when separate sequential scores for each of multiple subjects are entered as data points into subsequent inferential analyses. The problem is that the size of adjusted residuals will vary (become larger) as a function of the number of observations that are made, even when the actual conditional probabilities remain constant. Thus, the z-scores are influenced by the base rates of behaviors, and can differ dramatically across subjects when response productivity differs. Wampold (1989) recommends a transformed kappa statistic as an alternative; however, this statistic requires selecting among three different computational formulas depending on the relative size of expected and actual probabilities. Other commonly used statistics are Yule's Q and phi. Bakeman and Casey (1995) provide computational formulas, discuss the conditions under which various statistics may be applicable, and suggest that investigators examine the distributions of scores for each statistic to determine which statistic provides the best distribution of scores for a particular set of data.

Investigators are commonly concerned about the amount of data needed to calculate sequential statistics. This issue is most relevant when the investigator is interested in studying sequences involving relatively rare events. Unfortunately, clinically relevant phenomena are often rare phenomena, so the problem is a common one in the field of clinical psychology. Bakeman and Gottman (1997) present a detailed analysis of this issue using guidelines employed in log-linear analysis of contingency tables. As a general rule of thumb, the investigator should obtain enough data so that each antecedent and consequent event in a contingency table occurs at least five times. In many cases, this criterion can be met by collapsing codes into more general categories. Another strategy is to conduct analyses using pooled observations on a group of subjects, rather than calculating sequential statistics for individual subjects. For example, Gottman, Markman, and Notarius (1977) examined sequences of effective and ineffective problem solving in groups of distressed and nondistressed married couples. Although incidents of positive behaviors such as "validate" and negative behaviors such as "put-down" were rare in some couples, within the two groups they occurred with sufficient frequency to identify patterns of supportive interactions that were more typical of happily married couples, and patterns of hostile exchange that were more typical of spouses in distressed marriages.

3.01.8.2 Computer Technology for Recording and Coding Behavioral Observations

Since the late 1970s, computer technology has become increasingly available for use in recording and coding observational data. Whereas the use of devices and software requires extra initial costs in time and money, they may ultimately increase the efficiency of data collection, coding, and data management. If developers find a market for these devices, we can expect that their availability will become more widespread. Because specific products are likely to undergo rapid changes and development, a list of currently available products would be immediately out of date, and thus would be of little use. However, it is possible to illustrate the range of current options and some of the factors to consider in selecting equipment and software.

For most situations in which behavioral observation is used, the major function of automated systems is to record the observations and the codes reported by the human observer. Although Tryon (1991) catalogs many automated devices that actually measure "actions," most of these devices track physiological responses or simple, gross motor activity. To date, no automated system can code the types of complex events that are the focus of this chapter. The first systems designed for event recording were "dedicated devices" because their sole function was to aid in data collection. Data could be stored in a temporary system and then uploaded to a computer for analysis. These devices have been rapidly replaced by software systems that run on standard computers. The newest automated systems combine data entry and management functions with computer control of video playback devices.

One consideration in selecting a system is the number of codes the system can handle. For example, one software package, the Observational Data Acquisition Program (ODAP; Hetrick, Isenhart, Taylor & Sandman, 1991), allows for recording frequency and duration of up to 10 behaviors. Duration is recorded by depressing a key during the occurrence of a behavior. Taylor et al. (1991) used this system to measure six types of self-injurious behaviors. Although this system is easy to use, the major limitation is that only a circumscribed range of behavior can be evaluated with simple, one dimensional codes. In contrast, other systems allow the investigator to configure a data entry file to handle as many as 1000 codes, and the codes can be multifaceted. For example, the Observer system (Noldus, 1991) has the capacity to hold 1000 different codes which can be classified as occurring only under certain circumstances. The system prompts the coder to correct errors when codes that violate the classification structure are entered (e.g., the same behavior entered twice in systems where codes cannot repeat, or when a teacher code is assigned to a student). The Multiple Option Observation System for Experimental Studies (MOOSES; Tapp, Wehby, & Ellis, 1995) offers similar flexibility. In a study by Shores et al. (1993), MOOSES was used to record classroom interactions of children with behavior disorders. Codes were devised to indicate the actor, the behavior exhibited, and the recipient of the behavior. In addition, conditional variables such as the presence of a teacher or the grouping of students who were present were also recorded.

A second consideration is whether the system can interface with video playback devices. Several systems are available that link the computer with professional quality videotape players that include a computer interface port. A machine-readable time code is stamped on the videotape, and the computer reads the time code to track onset and offset times for events, duration for states, or to access specific intervals. The advantage of these systems over simple real-time recording devices is that the videotape can be stopped, reversed, and started repeatedly without needing to reset a timer. Examples are the Observer system (Noldus, 1991), Observation Coding System Toolset (OCS Tools; Triangle Research Collaborative, Inc, 1994), and Procoder (Tapp & Walden, 1993). These systems differ greatly in terms of the number and complexity of codes they can handle and the ability and ease of controlling the video player from the computer keyboard. More recently, packages are becoming available that use CD-ROM instead of videotape input (e.g., vPrism; Digital LAVA Inc., 1996). These systems provide easier access to specific sections of an observation session because of the digital access features of CD-ROM, and easier replay as compared to rewinding a video player. They may also allow for greater precision in labeling exact time segments. However, they require converting videotaped observations to compact disks, which is expensive when completed by companies that provide this service, and time-consuming when equipment is available for converting data in-house. Nevertheless, the reduced storage requirements for CDs as opposed to videotapes is an advantage.

A third consideration is the statistical analysis that a particular program may offer. Whereas some systems include software for calculating coder agreement, linking multiple channels (e.g., behavioral codes with heart rate data), and conducting sequential analyses, others output the data so that it can be imported into other programs for these purposes. Graphic presentation of data is also an option with some packages. In some cases, statistical programs are included as part of the basic system; in other instances, the statistical software is optional.

3.01.9 INTERPRETING DATA GATHERED THROUGH BEHAVIORAL OBSERVATION

As can be seen, there are a number of steps before investigators obtain findings based on behavioral observation. The final step for the investigator is interpreting these findings. Whereas this interpretive process is psychological in nature and dependent upon the specifics of the particular investigation, our own research on couples' relationships, marital therapy, and family development illustrates how a pattern of findings that include both behavioral observation and self-report measures can help to elucidate family/marital functioning.

Baucom and his colleagues have conducted several treatment outcome studies with maritally distressed couples from a cognitive-behavioral perspective. Cognitive-behavioral conceptualizations of marital distress have placed a major emphasis on the centrality of communication as essential for effective marital functioning. However, the pattern of findings across our investigations indicates that communications training might be neither necessary nor sufficient for affecting changes in marital functioning. In these investigations, couples' communication was assessed by the MICS III (Weiss, 1986) after the couples attempted to solve problems on areas of difficulty in their marriage in a laboratory setting. In the first study, all couples received some set of behavioral interventions to assist their marriages (Baucom, 1982). The difference among the treatment conditions involved whether the couples received communications training.

The findings indicated that couples in all of the active treatment conditions improved equally on communication and marital adjustment, suggesting that communications training was not the critical element in the treatment. In a subsequent investigation, Baucom, Sayers, and Sher (1990) provided maritally distressed couples with a variety of cognitive-behavioral interventions, but all couples received communications training. Again, the findings indicated that couples in all active treatment conditions improved equally on communication and marital adjustment. However, additional analyses indicated that changes in communication were not correlated with changes in marital adjustment; thus, communication training could not be interpreted as the critical ingredient that altered marital adjustment (Iverson & Baucom, 1990). This is not to say that communication is unimportant in marriage; a number of investigations indicates that it is (e.g., Gottman & Krokoff, 1989). However, the results from these investigations and others have led cognitive-behavioral investigators to develop more complex and multifaceted models of marital distress that include, but are not limited to, a communications skills deficit explanation (e.g., Karney & Bradbury, 1995). Thus, in this instance, the findings from investigations involving behavioral observation of communication with couples have led to theoretical changes in the conceptualization of marital adjustment.

Research by Floyd and colleagues investigates associations among subsystems within the families of children who have disabilities, and examines how family relationships predict adaptive functioning for the child and the other family members. All observations and data collection are conducted in the families' homes in order to maximize the likelihood that observed behaviors are relevant to daily functioning in the family. One set of reports (Floyd, Gilliom, & Costigan, in press; Floyd & Zmich, 1991) focuses on the hypothesis that the quality of the parents' marital functioning and their parenting alliance influence the quality of parenting experiences. In order to test the hypothesis, observational measures were combined with self-reports of both marital functioning and parenting experiences.

Similar to procedures commonly employed in studies of marital relationships, and as illustrated in the studies by Baucom and colleagues, the parents' marital problem-solving skills were assessed by having them discuss and attempt to resolve a significant area of disagreement in their relationship. This procedure linked the investigation to the large body of previous observational research on marriage and marital therapy. Also, because the focus of the study was to understand how the parents functioned as a marital dyad, the marital discussions were conducted in a room separate from the children. Other studies interested in how children witness marital conflict have used procedures where children are present either as observers or participants in the discussions (e.g., Cummings, 1987). In order to reduce reactive effects associated with the presence of a live observer, the couples were left alone together for 10 minutes to complete the discussion, and the discussions were videotaped for later coding.

Parenting experiences were evaluated in a separate family interaction session. The procedures for this session were adopted from the work of Patterson, Reid, and colleagues (Patterson, 1982; Patterson, Reid, & Dishion, 1992) with aggressive children and their families. These procedures had been used to identify how behavior management and control are disrupted, and lead to the escalation of negative exchanges in the families of aggressive children. Because children with mental retardation also present behavior management challenges for parents, the possibility of negative escalation was potentially relevant to these families. In order to make the interaction as naturalistic as possible, families were videotaped in the home while completing a task of their own choosing. All family members were present. However, it was also necessary to structure the session somewhat in order to ensure that the family members interacted together and that the videotapes were sufficiently clear so that the behaviors could be reliably coded. Thus, families were instructed to complete an activity together (e.g., baking cookies, working on a crafts project), to refrain from watching television or making or taking telephone calls, and to remain together in one or two rooms within range of the video camera. The families were observed for a total of 50 minutes, which, for coding purposes, was divided into 10 minute segments. During each segment, one family member was identified as the focus of coding, and only behaviors that occurred by the focus person and anyone interacting with that person were coded by the observer. This procedure allowed the camera operator to focus on subsets of family members rather than trying to keep all family members in view at all times.

The findings support the value of these observational methods. Most notably, whereas self-report measures of marital quality, the parenting alliance, and parenting experiences failed to distinguish families of children with mental retardation from a comparison group with typically developing children, both the marital interactions and the family interactions demonstrated greater marital negativity and more parent–child behavior management struggles for the MR group (Floyd & Zmich, 1991). Furthermore, negative marital interactions were predictive of negative parent–child exchanges. A subsequent longitudinal evaluation demonstrated that marital quality, including the quality of marital problem-solving interactions, predicts changes in negative parent–child exchanges over a two-year period, with couples who are most negative together showing increases in their negative exchanges with children over time (Floyd, Gilliom, & Costigan, in press).

3.01.10 CONCLUDING COMMENTS

As can be seen in the above discussion, behavioral observation provides an extremely rich source of information for investigators as they attempt to understand the complexities of human behavior and interaction. This richness presents many opportunities for investigators and many challenges as well. These challenges are incorporated in the myriad of decisions that the investigator must make in employing behavioral observation, and obviously the route that the investigator chooses greatly impacts the findings. Thus, the investigator incurs responsibility for understanding the impact of these decisions on the questions under investigation. Often in reporting the results of investigations employing behavioral observation, the method section of the report involving the application of coding systems and data analytic strategies is presented in a few short paragraphs. Consequently, most readers will have only a general level of understanding of how the coding system was employed and how that impacts the findings. Therefore, the investigator must thoroughly understand the coding process so that discussions of the findings accurately represent what is indicated by the data. When this is done in a thoughtful manner, we have the opportunity to use one of our most natural strategies, observing people's behavior, as a major way to advance the science of clinical psychology.

3.02.1 INTRODUCTION

The purpose of clinical research from the point of view of the consumer of research knowledge can be stated succinctly: "What treatment, by whom, is most effective for this individual with that specific problem under which set of circumstances, and how does it come about?" (Paul, 1969, p. 44). This question has always been of relevance to practicing clinical psychologists in the fee-for-service environment, but it is also of increasing relevance in the era of managed care. Mental health delivery systems cannot succeed, either in the world of public opinion or in the world of fiscal reality, without finding a way to deliver services that are both effective and efficient (Cummings, Cummings, & Johnson, 1997; Cummings, Pollack, & Cummings, 1996). In order to do that, Paul's clinical question above must be answered for the varieties of clients demanding and receiving services.

There is another way to say this. Clinical research must have external validity (must apply to the settings and clients of the research consumer), not merely internal validity (an unambiguous relationship between a dependent and independent variable). In group comparison research, external validity flows in principle from internal validity. In a classic group comparison design, researchers hope to randomly sample from a known population, randomly assign to a treatment and control group, and collect before and after measures on all. If these methodological requirements have been met, the results should apply to other random samples from that same population. In the practical world of clinical research, however, we do not have access to the entire population of interest (say, all panic disordered clients). We cannot randomly sample from this population because clients nonrandomly refuse to participate. We cannot randomly assign because clients nonrandomly drop out. And even if all this were not true, we never apply clinical research to other random samples from the same population—rather, a clinician treats the person who (nonrandomly) walked through the door.

External validity thus must be earned—whether in group comparison or single-case research—in a piecemeal inductive fashion by demonstrating that particular treatments work with particular clients with particular problems. In group comparison research, this is usually done by showing that treatments work in highly homogeneous groups of clients. By replicating effects across many such homogenous groups, external validity can be demonstrated in group research. Efforts to show broad external validity in a single group comparison experiment are usually extremely difficult. Blocking or stratifying samples on even a few factors in a single study can lead to huge designs that cannot be mounted without millions of dollars of research funds. One compromise is to use diagnostic categories as a way of establishing homogeneity; however, large and unexplained between-subject variation invariably results because the current diagnostic system is based on loose collections of signs and symptoms rather than functional processes.

An alternative approach is to build this knowledge base about treatment response from the ground up, person by person. In this approach, clinical replication across myriad clients provides the evidence that a treatment effect holds for a population and that it is moderated by specific subject, therapist, or setting variables. That is the approach of single case experimental designs (SCEDs) or what has also been termed "time-series designs." The former term is more popular but falsely suggests that the number of subjects is necessarily few in this approach. The latter correctly points to the source of the analysis but it is not very popular. Both terms will be used.

The purpose of this chapter is to show how single case designs are used in a research and practice environment, to provide an introduction to the various types of designs, and to explore the advantages of this research approach in the modern world of health care delivery.

3.02.1.1 Brief History of Single Case Experimental Designs

The origin of SCEDs in clinical psychology can be traced back to the beginnings of the scientist–practitioner model. Two years before at the first Boulder Conference, Thorne (1947) advocated the use of such designs as a practical way for clinicians to incorporate empirical science into their everyday interactions with clients, a goal concurrently explicated by Shakow et al. (1947). The type of experimental designs proposed by Thorne were a very significant improvement over the traditional case study because continual data collection over a series of phase changes were required, allowing more objective, data-driven decisions to be made. These designs were an adaptation of those previously used by experimental psychologists (Ferster & Skinner, 1957) working with animals.

Single case designs became considerably more popular with the popularization of behavioral approaches in the 1960s. For example, Baer, Wolf, and Risley (1968) described a number of these designs in an early issue of the *Journal of Applied Behavior Analysis*. Hersen and Barlow's groundbreaking text (1976) in turn brought these designs into the mainstream of behavior therapy.

Probably the biggest factors inhibiting the use of SCEDs by many clinicians has been a bias against ideographic research. Yet many methodological leaders of the field have been quite accepting of such an approach. For example, Cronbach (1975) advocated careful observation of individual clinical cases using SCED controls, maintaining that the use of such design tools allows a level of detail in observation and hypothesis testing not available in traditional group designs. Many others (Campbell, 1957; Koan & McGuire, 1973; Snow, 1974) have agreed, adding that tightly controlled, fixed condition, group experimentation is often not well-suited to a science of vastly differing humans with often vastly differing needs. Cone (1986) noted that ideographic, single-subject research is particularly well-suited for detecting point-to-point behavioral changes occurring in response to environmental variables, including psychological treatment.

3.02.1.2 Utility of Single-subject Designs

A clinician carefully conducting an appropriate single-subject design for a client could both circumvent the above difficulties and obtain scientifically useful results. Often no subject pool larger than one is needed to conduct a single-subject design (although it is necessary that the results of many such analysis be considered before any general conclusions can be made about a treatment's efficacy). Single-subject experiments are extremely flexible. For example, if a client is not responding as hoped to a treatment, components can be added or subtracted or an altogether new treatment can be implemented, without necessarily damaging the validity of conclusions drawn from the experiment. Essentially, the only limitation on the usefulness of single-subject designs in research and clinical practice is the flexibility of the researcher. If use of a planned design does not allow an adequate interpretation of emerging data, then the design can be altered at that point.

Perhaps more importantly, a properly used single-subject design can be extremely useful in facilitating responsible assessment and treatment. A clinician conducting a single-subject experiment is forced to pay close attention to repeated assessments of client behavior that provide invaluable information about target behaviors and treatment efficacy. With the continuous feedback that single-subject experiments provide, treatment components not working as planned can be altered, abandoned, or supplemented.

The comprehensive data recorded over several single-subject designs can also be used to provide linkage between client characteristics and treatment success or failure. As more detailed information is gathered in time-series designs than in a typical group experiment, events in individual client lives and various client characteristics that coincide with declines in treatment efficacy can be identified and taken into consideration for subsequent clients. The advantage at this level is that variability due to sources other than treatment can be identified at the level of the individual. This means that when many cases are collected and analyzed, correlations between subject characteristics and treatment responsiveness can be more refined. For example, it may become apparent after conducting several single-subject designs mapping the effects of a given intervention that subjects with certain characteristics respond in characteristically similar ways. Such a hypothesis can be followed up using additional single subjects, or by using a group design. Subjects that fail to respond positively to a given treatment may do so because of a detectable reason, and this reason may point to an important aspect of a relevant theory. Outcomes like this critically depend on the foresight of the researcher. Potentially important background data, as indicated by theory and common sense, should be collected in every single-subject experiment.

The use of time-series designs also compels a clinician to focus on the careful description of patient problems and treatment characteristics, and how this data relates to treatment outcome. In such a manner, variables that are functionally important for treatment can become evident. Over a series of SCEDs, generalizations concerning the active and efficacious components of treatment can be made from such data.

Finally, analysis of SCEDs concentrates on the magnitude of treatment effects rather than their statistical significance. If the treatment analyzed in a properly conducted SCED is clinically significant, it will be clearly so.

3.02.2 ESSENTIAL COMPONENTS OF SINGLE CASE EXPERIMENTAL DESIGNS

Although various types of individual time-series designs exist, and are discussed in some detail later, several procedures common to all time-series designs are first described.

3.02.2.1 Repeated Measurement

The bedrock of single case experimental designs is repeated measurements of client functioning taken in relevant domains throughout the course of treatment (Barlow & Hersen (1984), Hayes, Barlow, and Nelson (1997), and Kazdin (1980) give information on specific measurement strategies). Repeated measurements enable the estimation of variability within a case over time to provide the sources of information about treatment, measurement error, and extraneous factors in a time-series approach.

In the real world of clinical evaluation, the goal is to use measures that are both high quality and highly practical. It is advisable that such measurements begin as soon as possible, ideally during the first session. It is also advisable, in choosing which instruments to administer to the client or research subject, that the researcher err on the side of caution and administer as many instruments as may be even partially relevant to the current experiment's concerns. Theory and even common sense should be used to guide the choice as to what instruments are relevant. Practical constraints also play an important part. If an adequate but imperfect instrument already exists and no time is currently available to create a new one, the adequate instrument may be used. Client self-monitoring and self-report is entirely acceptable. In fact, any method of collecting data is acceptable with single-subject designs, so long as the researcher deems it appropriate. Flexibility, again, is the by-word. But, as with any instrument, pay attention to its established reliability and validity before using or interpreting data. As treatment progresses, instruments useless or irrelevant to the current case can be discarded, but data not initially gathered can never be collected. It is worth spending a little extra time administering an instrument on a hunch on the chance that it will yield valuable information. Measurements are then ideally administered as frequently as is practical and meaningful.

3.02.2.2 Detailed Information

Specification of the particular intervention made with the client, including when each component is delivered and any possibly significant deviations from the standardized treatment, allows meaningful inferences to be made from collected data. To be meaningful indicators of the effects of a treatment and its components, the clinician must be able to temporally link specific phases of their intervention with the ongoing flow of outcome data as described above. Details regarding the nature of the treatments, the environment that the therapy was delivered in, and characteristics of the therapist provide a level of detail conducive to proper replication, especially if the completed SCED is made available to others. Steps taken in group research to ensure treatment integrity can be taken here as well. For example, a colleague or student might be asked to assess a clinician's adherence to a designated treatment protocol, as well as the competence with which the treatment is delivered. Specification of the treatment requires that the researcher has a clear, theoretically-based idea of what they are attempting to accomplish and how to accomplish it. The type of treatment being used, its specific techniques, and the phases or subphases of each technique or strategy that are active should be noted. Enough detail should be added so that after the intervention is complete, an informed guess can be made as to what might have been responsible for observed effects.

Collection of detailed client information allows more meaningful inferences to be drawn from single-subject data. The recording of any information that might possibly affect the course and effectiveness of treatment may prove to be invaluable for data analysis. Seemingly relevant background information and significant events occurring in the client's life during the course of treatment qualify as important client information. If the client's spouse leaves her during the course of treatment, for example, notation of this event may serve as a possible explanation for a brief or sustained decline in the treatment's effectiveness. Of importance here is the chronicling of any information about the client or the client's life that might be expected to affect their response to treatment. Over a series of SCEDs, such information can be used to speculate as to why clients reacted differentially to treatment.

3.02.2.3 Graphing of Data

Analysis of an individual time-series design requires a visual representation of the data. A simple line graph, with time plotted on the x-axis and measurement score plotted on the y-axis, should be sufficient for most data because it presents an immediate picture of variability within a data series. Pragmatic considerations determine what unit of time to plot. Thus, if an instrument is measuring behaviors in frequent time intervals but the behavior itself is better thought of in temporally larger units, analysis may be facilitated if time intervals are collapsed (e.g., if daily measurements are summed and recorded as weekly measurements). Frequent and creative graphing of data, from various angles, using different units of time, composite scores from separate measures, etc., can allow insights into the effects of treatment.

3.02.2.4 Creative Use of Design Elements

Individual time-series design elements (discussed below) should be thought of as tools, not restrictive agents. If a complex phase change with an interaction element is initially planned, and the data indicates the client might benefit most from continuing with the current treatment, then continuation of treatment is clearly justified. Unexpected client or therapist vacations can be an opportunity for a return to baseline phase, allowing a chance to monitor the effectiveness, in contrast, of treatment. Clinical common sense and detailed understanding of the nature of the different design elements and when they are useful allows effective and serendipitous adaptation to events.

3.02.3 INTERPRETATION OF SINGLE-SUBJECT DATA

Time-series designs typically (though not always) consist of units of time called phases, each phase designating the continuous presence of a given condition (e.g., treatment, baseline, and so on). Data within each phase can be described as having various degrees of variability around a given level and trend. Use of statistical analyses is not necessary at the level of the individual, and indeed use of most inferential statistics with a single subject violates the assumptions of standard statistical tests. Clear graphing of data and a thorough understanding of interpreting such single-subject graphs are all that are needed to observe an effect. It is to the nature of variability, level, and trend, and to the opportunities they provide for the interpretation of the data, that we now turn.

3.02.3.1 Variability and Stability

Data within a phase is said to be stable to the extent that the effects of extraneous variables and measurement error, as reflected in variability within a subject across time, are sufficiently limited or identifiable that variability due to treatment can be ascertained. Determining stability requires that the clinician have some clarity about what treatment effects are large enough to be worth detection—the more variability due to extraneous factors or measurement error, the larger the treatment effect would have to be to be seen.

If the data are not stable (in the sense that important treatment effects might be obscured), the experimenter can (i) continue the phase until the data does become stable, (ii) examine the data using longer units of time if longer units are more sensible, or (iii) analyze the possible sources of variability. Each of these is defensible, but the last option is often the best because it can provide important information about the case.

3.02.3.2 Level

Level refers to the "height" on the y-axis at which the data tends to aggregate. For example, data taken during a treatment phase tending to stay at the upper points of the measurement scale would be notably distinguishable, in terms of level, from data congregating around the mid-point of a measurement scale.

3.02.3.3 Trend

Trend refers to the general linear direction in which data are moving across a given period of time. It takes a minimum of three data points to establish a trend and estimate variability around that trend.

Converging and diverging trends between phases can be analyzed to help differentiate variability due to treatment from variability due to extraneous sources. For example, if a client's data on a given measure shows a positive trend in baseline that continues when treatment is implemented and continues yet again when the baseline is reinstated, it is likely that something other than treatment is responsible for the improvement. Conversely, if a strong positive trend during a treatment phase levels out or especially reverses after a change to a baseline phase, the clinician can usually feel confident that treatment is responsible for the change (unless some potentially significant life change happened to co-occur with the phase change). Thus, trends are not only useful indicators as to the improvement or decline of clients on various measures, but are also useful indicators, coupled with phase changes, of the sources of those changes.

3.02.3.4 Use of Statistics with Single-subject Data

For the most part, inferential statistics were designed for use in between-group comparisons. The assumptions underlying the widely accepted classical model of statistics are usually violated when statistical tests based on the model are applied to single-subject data. To begin with, presentation of conditions is not generally random in single-subject designs, and randomization is a necessary prerequisite to statistical analysis. More importantly (and more constantly), the independence of data required in classical statistics is generally not achieved when statistical analyses are applied to time-series data from a single subject (Sharpley & Alavosius, 1988). Busk and Marascuilo (1988) found, in a review of 101 baselines and 125 intervention phases from various single-subject experiments, that autocorrelations between data, in most cases, were significantly greater than zero and detectable even in cases of low statistical power. Several researchers have suggested using analyses based on a randomization task to circumvent the autocorrelation problem (Edgington, 1980; Levin, Marascuilo, & Hubert, 1978; Wampold & Furlong, 1981). For example, data from an alternating treatment design or extended complex phase change design, where the presentation of each phase is randomly determined, could be statistically analyzed by a procedure based on a randomization task. Some controversy surrounds the issue (Huitema, 1988), but the consensus seems to be that classical statistical analyses are too risky to use in individual time-series data unless at least 35–40 data points per phase are gathered (Horne, Yang, & Ware, 1982). Very few researchers have the good fortune to collect so much data.

Time-series analyses where collected data is simply used to predict subsequent behavior (Gottman, 1981; Gottman & Glass, 1978) can also be used, and is useful when such predictions are desired. However, such an analysis is not suitable for series with less than 20 points, as serial dependence and other factors will contribute to an overinflated alpha in such cases (Greenwood & Matyas, 1990). In cases where statistical analysis indicates the data is not autocorrelated, basic inferential statistical procedures such as a *t*-test may be used. Finally, the Box–Jenkins procedure (Box & Jenkins, 1976) can technically be used to determine the presence of a main effect based on the departure of observed data from an established pattern. However, this procedure would require a minimum of about 50 data points per phase, and thus is impractical for all but a few single-subject analyses.

In addition, most statistical procedures are of unknown utility when used with single-subject data. As most statistical procedures and interpretations of respective statistical results were derived from between-group studies, use of these procedures in single-subject designs yields ambiguous results. The meaning of a statistically significant result with a lone subject does not mean the same thing as a statistically significant result with a group, and the assumptions and evidentiary base supporting classical statistics simply dose not tell us what a significant result with a single subject means. Beyond the technical incorrectness of using nomethetic statistical approaches to ideographic data, it is apparent that such use of these statistics is of extremely limited use in guiding further research and bolstering confidence about an intervention's efficacy with an individual subject. If, for example, a statistically significant result were to be obtained in the treatment of a given client, this would tell us nothing about that treatment's efficacy with other potential clients. Moreover, data indicating a clinically significant change in a single client would be readily observable in a well-conducted and properly graphed single-subject experiment. Statistics—so necessary in detecting an overall positive effect in a group of subjects where some improved, some worsened, and some remained unchanged—would not be necessary in the case of one subject exhibiting one trend at any given time.

3.02.4 VARIETIES OF SINGLE-SUBJECT DESIGNS

Time-series design elements can be classified either as within-series, between-series, or combined-series designs. Different types of time-series design elements within each group of designs are used for different purposes (Hayes et al., 1997). The nature of each type of element, as well as its purpose, will now be described.

3.02.4.1 Within-series Design Elements

A design element is classified as within-series if data points organized sequentially within a consistent condition are compared to other such sequential series that precede and follow. In such a design, the clinician is typically faced with a graphed data from a single measure or a homogenous group of measures, organized into a sequence of phases during which a consistent approach is applied. Phase changes occur, ideally, when data has stabilized. Otherwise, practical or ethical issues determine the time at which phases must change. For example, an extended baseline with a suicidal client would certainly not be possible, and time and financial constraints may determine phase changes in other cases. Aspects of specific design strategies that influence phase length are discussed at the appropriate points below.

Within-series design elements include the simple phase change, the complex phase change, the parametric design elements, and the changing criterion design. Each is described below. Note that specific phases are designated below by capital letters. Generally (but not always), the letter A refers to a baseline phase, and letters such as B and C refer to different interventions.

3.02.4.1.1 Simple phase change

If simply trying to determine a treatment's efficacy vs. no treatment at all for a given client, or comparing the relative efficacy of two validated treatments for a given client, then a simple phase change design is probably the right choice. Consider the case in which only a single treatment's efficacy is at issue. A similar approach can be taken to answer questions about the relative efficacy of two treatments.

In the standard simple phase change, baseline data on relevant client behaviors is typically taken for a period of time (enough time to estimate the level, trend, and variability around level and trend of the behavior of interest). This baseline phase can occur during initial sessions with the client while assessment (and no treatment *per se*) is taking place, while the client is on a waiting list, or through similar means. Treatment is then administered and while it is in place a second estimate is made of the level, trend, and variability around level and trend of the behavior of interest. If clear changes occur, treatment may have had an impact.

In order to control for extraneous events that might have co-occurred with the phase change from baseline to treatment, the phase change must be replicated. Usually this is done by changing from treatment back to baseline, but other options exist. Such a change, called a withdrawal, is useful in aiding the clinician in deciding whether it is indeed the treatment, and not some extraneous variable, that is responsible for any changes. However, certain ethical considerations must be made before a withdrawal is executed. If treatment definitely seems effective and is well-validated, it may not be necessary to withdraw the treatment to conclude that a treatment effect is likely. If the clinician is uncertain of the treatment's effectiveness, or if it is not well-validated, a withdrawal or some other means of replication is necessary in order to conclude that an effect has occurred. Even a short withdrawal can be sufficient if a clear trend is evident. Alternatively, a period of time where therapy is focused on a different, relatively unrelated problem can also be considered a withdrawal. Serendipitous opportunities for a return to a baseline phase can provide important information. Impromptu client or therapist vacations can be viewed as a chance to make more informed decisions regarding the treatment's efficacy.

More than one replication of the underlying phase change (such as an ABABAB design) may be necessary for the clinician to be confident of a treatment's effects for a particular client. Interpretation of the data is facilitated by referring to the specifics of stability, level and trends as discussed above.

Examples of well-conducted simple phase change designs include Gunter, Shores, Denny, and DePaepe (1994), who utilized the design to evaluate the effects of different instructional interactions on the disruptive behavior of a severely behaviorally disordered child. Gunter et al. (1994) used a simple phase change with reversal (in this case ABAB), with baseline or A phase consisting of a math assignment with between five and 15 difficult multiplication problems. The treatment or B phase consisted of equally difficult problems, but the experimenter would provide the correct answer and then present the same problem again whenever the subject incorrectly answered. Institution of the first treatment phase indicated a desirable effect, with the subject's rate of disruptive behavior falling from around 0.3 to around 0.1. Gunter et al. (1994) wisely decided to replicate the phase changes with the subject, allowing them to be more confident that extraneous variables such as time or (to some extent) order were not responsible for the changes.

Orsborn, Patrick, Dixon, and Moore (1995) provide another good, contemporary example of the simple phase change design (Figure 1). They used an ABAB design to evaluate the effect of reducing the frequency of teacher's questions and increasing the frequency of pauses on the frequency of student talk, using 21 first- and second-grade subjects. Both B phases showed a marked increase in student talk frequency relative to baseline phases. The strength of the design, however, could have been improved with the inclusion of more data points. Five data points were collected during baseline phases, and three in intervention phases. Three is an acceptable minimum, but more data points are advisable.

3.02.4.1.2 Complex phase change elements

A complex phase change combines a specific sequence of simple phase changes into a new logical whole.

(i) ABACA

When comparing the effectiveness of two (or more) treatments relative to each other and to

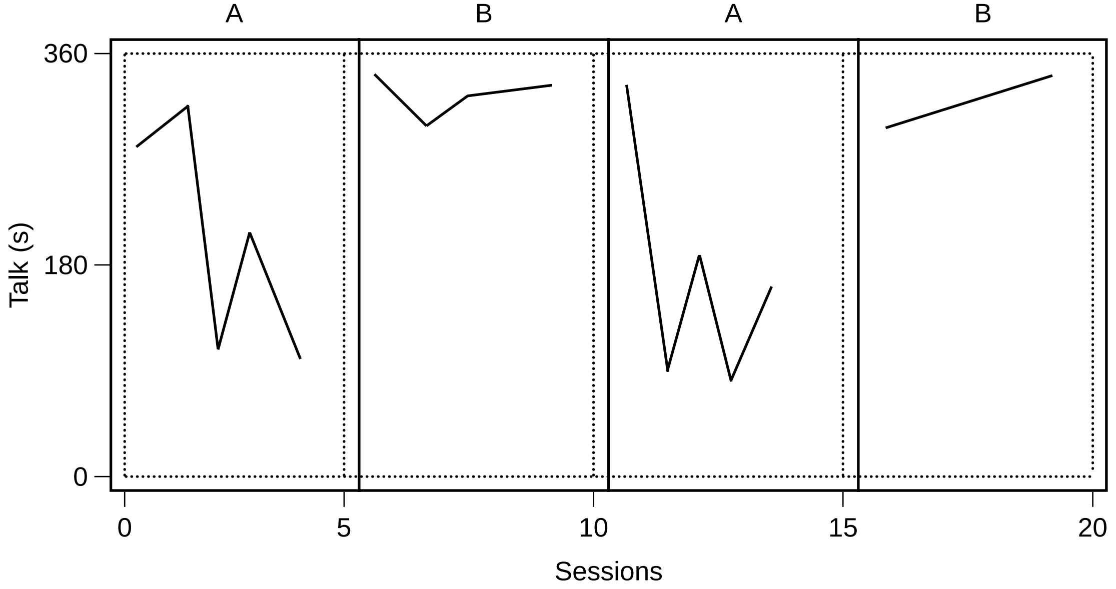

Figure 1 An adaptation of a simple phase change with reversal design. Data were relatively stable before phase changes (adapted from Orsborn et al., 1995).

no treatment, an ABACA complex phase change element might be used. Typically, the clinician would choose such a design when there is reason to believe that two treatments, neither yet well-validated, may be effective for a given client. When it is unclear whether either treatment will be effective, treatment phases can be interspersed with baseline phases. Phase changes conducted in such a manner will allow meaningful comparisons to be made between both treatments, as well as between each treatment and no treatment. After administering each treatment once, if one that results in clearly more desirable data level and trend, it may be reinstated. If each treatment's relative efficacy is still unclear, and the data gives no reason to believe that either may be iatrogenic, phase changes may be carried out as is practical. A sequence such as ABACACAB might not be unreasonable if the data and clinical situation warranted. Regardless of the sequence implemented, the clinician should remain aware that order effects in a complex phase change can be critical. The second treatment administered may be less effective simply because it is the second treatment. Counterbalancing of phase sequences in other cases can circumvent such ambiguity.

The clinician should stay alert to the possibility of introducing even a third treatment in such a design, if the original treatments do not appear to be having the desired effect. An example of such a situation is shown in a study by Cope, Moy, and Grossnickle (1988). In this study, McDonald's restaurants promoted the use of seat belts with an advertising campaign (phase B), and the distribution of instructive stickers for children asking them to "Make it Click" (phase C). These two interventions were tried repeatedly. Finally, an incentive program was implemented giving away soft drinks for drivers who arrived at McDonald's with their seat belt fastened. The design could be described as an ABCBCBDA. The spirit here, as always when using time-series approaches, should be one of flexible and data-driven decisions. With such a spirit, the clinician should be willing to abandon even an empirically validated treatment if it is clear, over a reasonable length of time, that there is no positive effect. No treatment is all things to all people.

Another well-conducted complex phase change design was reported by Peterson and Azrin (1992; Figure 2). Three treatments, including self-monitoring (phase B), relaxation training (phase C), and habit reversal (phase D), were compared with a baseline or no treatment (phase A). Six subjects were used, and the authors took advantage of the extra subjects by counterbalancing the presentation of phases. For example, while the first subject was presented with the phase sequence AAABCDCBDA, other subjects were presented with sequences such as AAADCBCD-BA, AAACDBDCBA, and AAACDBDCBA. A minimum of three data points were contained in each phase (generally four or more data points were used), and the authors more often than not waited until stability was achieved and clear trends were present before changing phases for subjects.

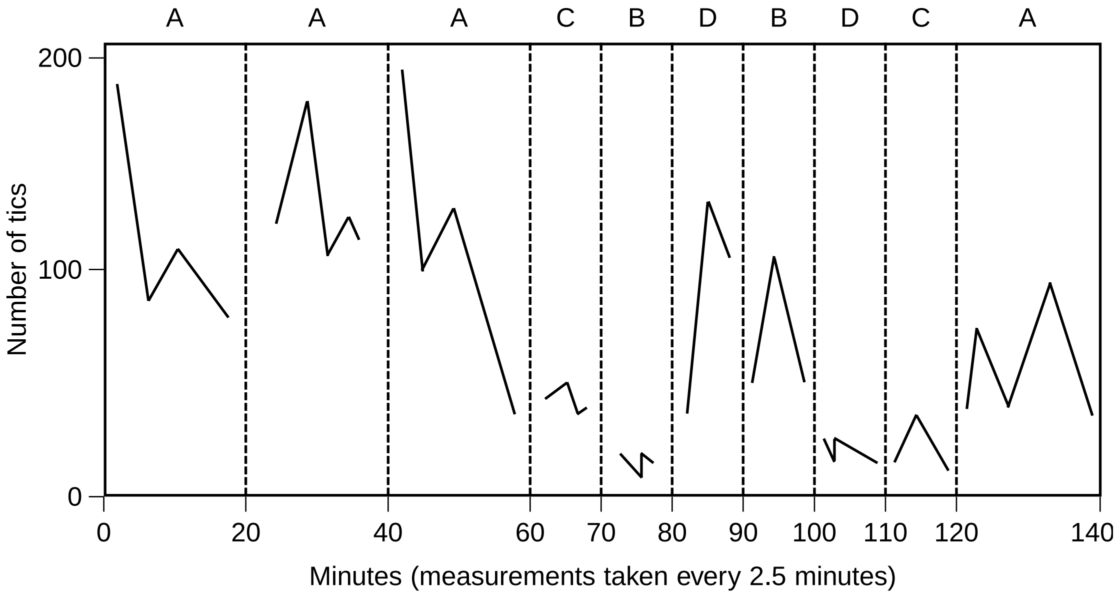

Figure 2 An example of a complex phase change. Waiting for the data in the first and third baseline (A) phase to stabilize (as well as the data in the first D phase) would have been preferable before initiating phase changes (adapted from Peterson and Azrin, 1992).

(ii) Interaction element

In an interaction element the separate and combined effects of intervention elements are examined. Use of this design element is appropriate both when a treatment is working and the clinician wishes to ascertain whether it will continue working without a particular (and costly in terms of time and/or money) component, or when a treatment is not maximally effective and the clinician believes adding or subtracting a specific component might enhance the treatment's efficacy.

White, Mathews, and Fawcett (1989) provide an example of the use of the interaction element. They examined the effect of contingencies for wheelchair push-ups designed to avoid the development of pressure sores in disabled children. Wheelchair push-ups were automatically recorded by a computer. After a baseline, two subjects were exposed to an alarm avoidance contingency (B), a beeper prompt (C), or a combination. An interaction design element was combined with a multiple baseline component. The design for one subject was an A/B + C/B/B + C/B/B + C/C/B + C, and for the other was A/B + C/C/B + C/C/B + C. Each component (B or C) was more effective than a baseline, but for both children the combined (B + C) condition was the most effective overall.

Shukla and Albin (1996) provided another good example when examining the effects of extinction vs. the effects of extinction plus functional communication training on problem behaviors of severely disabled subjects (Figure 3). Extinction had previously been found to be effective in reducing the frequency of target behaviors, but it had the unfortunate effect of sometimes causing more problematic behaviors to emerge. By alternating phases consisting of extinction alone and extinction plus communication training, the authors were able to show that the second condition resulted in uniform decreases in problematic behavior.

(iii) Changing criterion

The changing criterion design element consists of a series of shifts in an expected benchmark for behavior, such that the correspondence between these shifts and changes in behavior can be assessed. It is particularly useful in the case of behaviors that tend to change gradually, provided that some benchmark, goal, criterion, or contingency is a key component of treatment.

The establishment of increasingly strict limits on the number of times a client smokes per day provides a simple example. A changing criterion design could be implemented when it is unclear as to whether the criteria themselves, and no other variable, were responsible for observed changes in smoking. As another example, a changing criterion design could be implemented to assess the degree to which changing minimum numbers of social contacts per day affects actual social contacts in a socially withdrawn client.

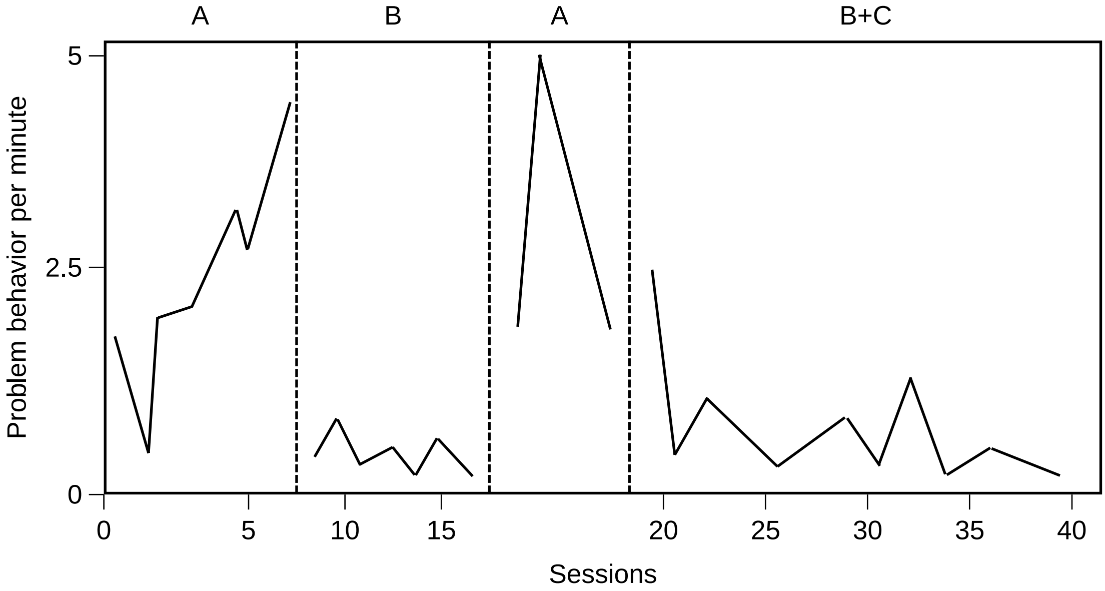

Figure 3 An interaction element design. The interaction (B + C) condition did not yield a better result than the B condition, but the demonstration of no further efficacy was still an important finding (adapted from Shukla & Albin, 1996).

In order to maximize the possibility that the data from a changing criterion design are correctly interpreted, five heuristics seem useful. First, the number of criterion shifts in the design should be relatively high. Each criterion shift is a replication of the effect of setting a criterion on subsequent client behavior. As with any type of experiment, the more frequently the results are replicated, the more confident the researcher can be of the effect and its causes. As a rule of thumb, four or more criterion shifts should occur when a changing criterion design is implemented.

Second, the length of the phase in which one level of the criterion is in effect should be long enough to allow the stability, level, and trend of the data to be interpreted relative to the criterion. Additionally, if a clear trend and level do not initially emerge, the criterion should remain in effect until a clear trend and level does emerge. Belles and Bradlyn (1987) provide a good example of properly timed criterion changes. The goal was to reduce the smoking rate of a long-time smoker who smoked several packs a day. The client recorded the number of cigarettes smoked each day (with reliability checks by the spouse). After a baseline period, goals were set by the therapist for the maximum number of cigarettes to be smoked. If the criterion was exceeded, the client sent a $25 check to a disliked charity. For each day the criterion was not exceeded, $3 went into a fund that could be used to purchase desirable items. Each criterion was left in place for at least three days, and the length of time, magnitude, and direction of criterion shifts varied. It should also be noted that, as in the Belles and Bradlyn (1987) study, criterion changes should occur at irregular intervals. As certain behaviors may change in a cyclical or gradual manner naturally, criteria should be shifted after differing lengths of time. Thus, if the length of one criterion's phase happens to correspond to changes occurring naturally, the phase lengths of other levels of the criterion will be unlikely to continue this trend.

Third, criterion changes should occur at irregular intervals. As certain behaviors may change in a cyclical or gradual manner naturally, criteria should be shifted after differing lengths of time. Thus, if the length of one criterion's phase happens to correspond to changes occurring naturally, the phase lengths of other levels of the criterion will be unlikely to continue this trend.

Fourth, the magnitude of criterion shifts should be altered. If the data can be shown to track criterion changes of differing magnitudes, the statement that the criterion itself is responsible for observed changes can be made with a greater level of assurance.

Finally, a periodic changing of the direction of criterion shifts can be useful in assisting interpretations of effects. Such a strategy is similar to the reversal common in simple and complex phase changes. If client behavior can be shown to systematically track increasing and decreasing criteria, the data can be more confidently interpreted to indicate a clear effect of the changing criteria on those behavioral changes.

DeLuca and Holborn (1992) used the changing criterion design in analyzing the effects of a variable-ratio schedule on weight loss in obese and nonobese subjects (Figure 4). Phase sequences consisted of a baseline (no treatment) phase, three different criterion phases, an additional baseline phase, and finally a return to the third criterion phase. The criterion involved the number of revolutions completed on a stationary exercise bike during the allotted time in each phase. Criterion phases were determined by a calculation of 15% over the criterion in place for the previous phase; when the criterion was met, a subject would receive reinforcement in the form of tokens exchangeable for established reinforcers. Each phase (except for the five-session final phase) lasted for eight 30-minute sessions, resulting in eight data points per phase. The increasing variable ratio schedules were shown, through use of this design, to exert control over increased frequencies of revolution. Although the design did not exhibit some typical features of the changing criterion design, such as staggered phase length, criterion direction reversals, and varying phase change depths, the observation of clear effects were facilitated by the return to baseline phase and subsequent replication of the third criterion phase. In addition, the use of the design in an exercise program was prudent, as exercise involves gradual performance improvements of a type easily detected by the changing criterion design.

3.02.4.1.3 Parametric design

When it is suspected that different levels or frequencies of a component of an intervention might have a differential effect on client behavior, a parametric design can be implemented. Such designs are frequently used to assess the effects of different psychotropic drug dosages, but design is relevant for many other purposes. Kornet, Goosen, and Van Ree (1991) demonstrated the use of the parametric design in investigating the effects of Naltrexone on alcohol consumption.

Ideally, a kind of reversal can be incorporated into a parametric design, where levels of the independent variable in question were systematically increased and then decreased. As with the changing criterion element, showing that an effect tracks a raised and lowered standard bolsters the confidence with which an interpretation is made. Baseline data should usually be taken before and after changes in the parameter of interest. If certain levels of the parameter provide interesting or unclear data, alternations between those levels, even if not originally planned, can aid in clarification (e.g., if the sequence A/B/B′/B″/B‴/B″/B′/B/A was originally planned and the data spurs increased interest in the B and B′ levels, a sequence such as B/B′/B/B′ could be inserted or added).

An example of acceptable use of parametric design is provided by Stavinoah, Zlomke, Adams, and Lytton (1996). The experimenters

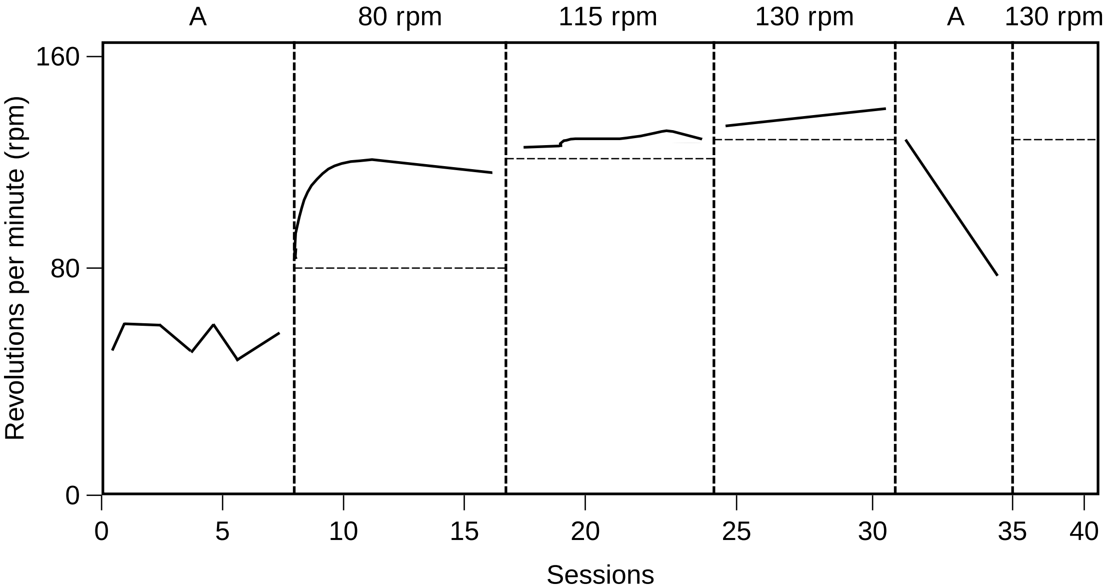

Figure 4 An example of a changing criterion design. Dotted horizontal lines indicate set criterion in each phase. The use of more than three criteria might have been preferable to further indicate experimental control over behavior, but the design seems adequate nonetheless (taken from DeLuca & Holborn, 1992).

systematically varied dosages of haloperidol and fluoxetine while measuring the frequency of the subject's impulsive aggressive behaviors (IABs). Dosages of haloperidol ranged from about 40 mg to 20 mg over the 40 weeks that it was administered. As a 40 mg dose initially resulted in an average of 10 IABs per week, dosage was reduced to 20 mg after 12 weeks. During the next 34 weeks, IABs increased to 13 per week, and the decision was made to increase the dosage back to 40 mg. This resulted in an average of 45 IABs per week for the four weeks this dosage was in place. The experimenters then administered a 20 mg dose of fluoxetine for the next 62 weeks, resulting in an average IAB frequency of near zero. A 40 mg dose of fluoxetine administered for 58 weeks yielded IAB frequencies of near zero. A subsequent reduction to 20 mg for five weeks resulted in an average IAB frequency of 12; the dosage was then returned to 40 mg, with a resulting IAB frequency of almost zero. Ideally, less time could have been spent at each dosage, and a greater variety of dosages could have been employed. But the experimenters did vary dosage and even drugs, and did so with a sufficient number of data points to determine the effect each drug and dosage had on behavior.

Lerman and Iwata (1996) provide a better example of use of the parametric design in treating the chronic hand mouthing of a profoundly retarded man (Figure 5). Sessions were conducted two or three times per day. Baseline frequencies (with no attempts to stop the hand mouthing behavior) were first calculated; baseline rates of three times per minute, on average, were recorded over several sessions. During the intervention phase, all subject attempts at hand mouthing were blocked by the experimenter putting his hand in front of the subject's mouth, resulting in less than one instance of hand mouthing per minute. Subsequently, attempts were blocked at a ratio of 1 block per 2 attempts, 1/4, 1/2, 2/3, and 3/4. The frequency of hand mouthing remained near zero over all levels. The experimenters properly used a descending/ascending order for levels, but also allowed subject behavior to determine what blocking schedule would be used. The experimenters thus remained responsive to the data, and their efforts yielded a less intensive intervention than one block per attempt.

3.02.4.1.4 Final suggestions for interpreting within-series data

Besides the suggestions listed above for interpreting various types of within-series data, additional general suggestions are offered here. First, as with any type of data-producing procedure, replicated effects are always more believable than nonreplicated effects. If an effect is consistently duplicated across several clients or across several different behaviors in the same client, the clinician can feel more confident in stating that the treatment in question is responsible for the effect. Each additional reinstatement of a treatment phase resulting in client improvement within a single series of data should also allow more confident statements about that treatment's efficacy with that client to be made. Second, effects are much more believable to the extent that they occur in a consistent manner. Third, changes of a greater magnitude (when parsing out changes apparently caused by extraneous variables) should generally be taken as more robust evidence of the treatment's effects. Fourth, effects occurring immediately after the onset of a treatment phase are logically stronger indicators that the treatment is responsible for the changes than are delayed effects, since fewer alternative explanations exist for the effects seen. Fifth, greater changes in the level and trend of the data are generally more indicative of a treatment's efficacy. Sixth, any effects not explainable by variables other than treatment should naturally be more convincing. Finally, all effects should be interpreted while considering the background variability of the data. The variability in the data around a given level and trends in a consistent condition provide an individual estimate of the impact of extraneous factors and measurement error against which any treatment effect is seen. If, for example, the level and/or trend of baseline data at times overlaps with the level and/or trend of treatment phase data, the clear possibility that factors other than treatment may be augmenting (or inhibiting) the treatment effect should be considered.

Brief mention of some commonly occurring conditions illustrate application of the guidelines discussed thus far. If a significant upward or downward data trend begins one to three data points before a phase change is planned, delay of the phase change until the data stabilizes is suggested. A trend is significant if it is of a greater degree than changes attributable to background variability, such as would be observed when a series of relatively stable data fluctuates around an average level. However, if an established and significant trend has emerged over a few (e.g., three or more) data points, a phase change might be acceptable if such results had been expected. Instability and unclear trends are obviously of less importance at the beginning of a phase than at the end; data at first uninterpretable often has a way of telling a clearer story after more data is collected. The

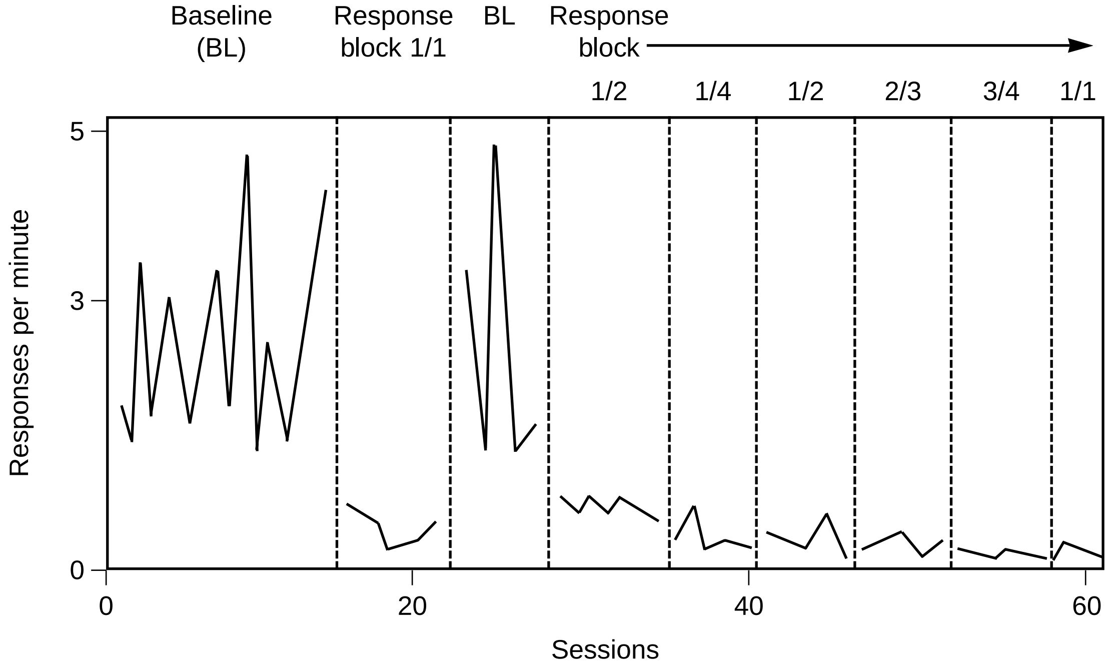

Figure 5 An example of a parametric design. Response block conditions refer to differing levels of intervention, that is, 14 translates to one response block per every four handmouthing attempts (adapted from Lerman & Iwata, 1996).

value of collecting as many data points as feasible (e.g., seven or more) becomes clear after only a few data points have been graphed.

3.02.4.2 Between-series Designs

Within-series designs involve comparisons of sequences of repeated measurements in a succession of consistent conditions. Between-series designs are based on a comparison of conditions that are concurrent or rapidly alternating, so that multiple data series are simultaneously created. Pure between-series designs consist of the alternating treatments design and the simultaneous treatment design.

3.02.4.2.1 Alternating treatment design

The alternating treatment design (ATD) consists of rapid and random or semirandom alteration of two or more conditions such that each has an approximately equal probability of being present during each measurement opportunity. As an example, it was observed during a clinical training case that a student therapist, during many sessions, would alternate between two conditions: leaning away from the client and becoming cold and predictable when he was uncomfortable, and leaning towards the client and becoming warm and open when feeling comfortable. The client would disclose less when the therapist leaned away, and more when he leaned forward. If it were assumed that the therapist had preplanned the within-session alternations, an ATD as shown in Figure 6 would be obtained. The condition present in the example at any given time of measurement is rapidly alternating. No phase exists; however, if the data in each respective treatment condition are examined separately, the relative level and trend of each condition can be compared between the two data series (hence the name between-series designs).

An example of the ATD is provided by Jordan, Singh, and Repp (1989). In this study, two methods of reducing stereotypical behavior (e.g., rocking, hand-flapping) in retarded subjects were examined: gentle reaching (the use of social bonding and gentle persuasion with the developmentally disabled) and visual screening (covering the client's eyes for a few seconds following stereotypic behavior, thus reducing visual stimulation including that provided by these movements). Each of the two conditions were randomly alternated with a baseline condition. After a baseline period, visual screening produced a dramatic reduction in stereotypy, whereas gentle teaching had only a transient effect.

Another proper use of the alternating treatments design is provided by Van Houten (1993; Figure 7). Four children were taught subtraction using two different procedures (one procedure involved the use of a general rule,

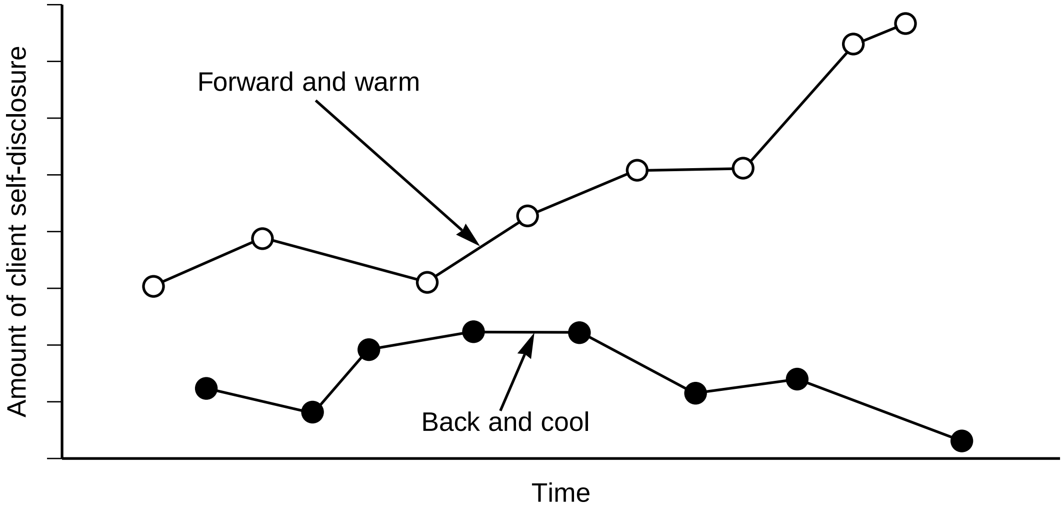

Figure 6 A hypothetical example of the use of an ATD to assess the effects of therapist behavior on client self-disclosure.

the other involved only rote learning). Use of the procedures was alternated randomly and every 15 minutes over the length of 15 or more sessions, and the subtraction problems used in each session were counterbalanced across the subjects so that effects could be attributed to the teaching methods and not the problem sets. The use of an ATD rather than a complex phase change was prudent, as the order the methods were presented in longer phases could probably have exerted a practice effect.

One of the benefits of the ATD is the simplicity with which it can be used to compare three or even more treatment conditions. Proper comparisons of three conditions in a within-series design can be difficult due to counterbalancing concerns, order effects, and the sheer number of phase changes that need to be executed over a relatively long period of time. With an ATD, three or even more conditions can be presented in a short time. The rapid and random alternations between conditions makes order effects less likely, but multiple treatment interference (the impact of one treatment is different due to the presence of another) is arguably likely. ATDs are ideally used with behaviors emitted at a relatively high frequency that correspondingly allows many instances of each alternate intervention to be applied. However, the design may be used with relatively infrequent behaviors if data is collected for a longer period of time. In addition, behaviors that tend not to have an impact for long after a discrete intervention is made and withdrawn make better targets for an ATD. If a change initiated by such a discrete intervention continues over a long period of time, effects of subsequent interventions are obscured and reliable data interpretation is often not possible.

ATDs hold several other advantages over standard within-series designs. First, treatment need not be withdrawn in an ATD—if treatment is periodically withdrawn, it can be for relatively short periods of time. Second, comparisons between components can be made more quickly. If a clear favorite emerges early in a well-conducted ATD, the clinician can be reasonably sure that its comparative efficacy will be maintained McCullough, Cornell, McDaniel, and Mueller (1974), for example, compared the relative efficacy of two treatments in four days using an ATD. ATDs can be used without collecting baseline data, or with baseline data through the creation of a concurrent baseline data series. Any background within-series trends (such as those due to maturation of the client or etiology of the disorder) are unlikely to obscure interpretation of the data because the source of data comparisons are purely between series, not within.

ATD requires a minimum of two alterations per data series. As both series can be combined to assist assessments of measurement error and extraneous factors, the number of data points required is less than with a within-series design. The collection of more than two data points per series is typical and highly useful, however. In a sense, each alternation is a replication and conclusions from all time-series designs can be stated with more confidence with each consistent replication.

When planning alternations, the clinician should be alert to the duration, after presentation, of a component's effect. An administered drug, for example, exerts an effect over a period of time, and presenting a new treatment component before that time has expired would confound interpretation.

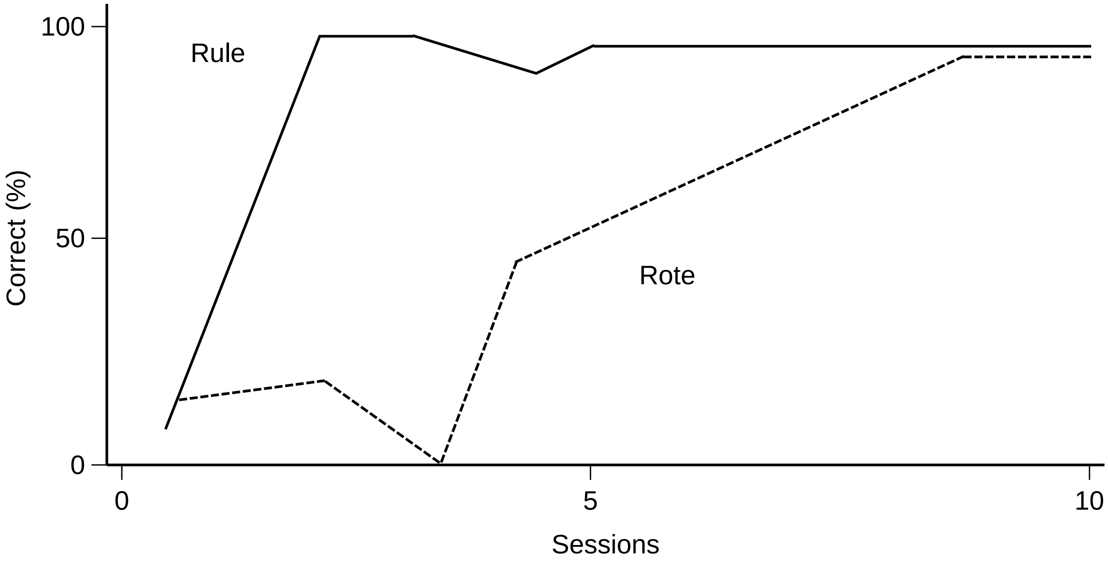

Figure 7 An ATD in which rule-learning trials are interspersed with rote-learning trials. A practice or generalization effect is apparent in the rote-learning condition beginning around session 8 (adapted from Van Houten, 1993).

One of the shortcomings of the ATD is that observed effects in the design can be due to the way in which conditions are presented and combined. Three areas of concern in this domain of multiple treatment interference are sequential confounding, carry-over effects, and alternation effects (Barlow & Hayes, 1979; Ullman & Sulzer-Aszaroff, 1975).

Sequential confounding occurs when there is a possibility that a treatment condition A yields different effects when presented before a treatment condition B than it does when presented after condition B. To control for sequential confounding, the clinician is encouraged to alternate treatment conditions randomly or at least semirandomly. With a randomly delivered sequence such as ABBBAABABBBABBAAAABBAAABAA, if consistent differences between each condition's effects continue to show up throughout the sequence, despite the fact that the order and frequency of each conditions' presence differs through the sequence, the clinician can be relatively certain that observed effects are not an artifact of order of condition presentation.

A carry-over effect occurs when the presentation of one condition somehow affects the impact of the subsequent condition, regardless of the presentation order of the conditions. Potentially this can occur in two ways. The effects of two conditions can change in opposite directions, or in the same direction. For example, when a strong reinforcer is delivered after a weak reinforcer, the weak reinforcer can subsequently cease to reinforce the desired behavior at all while the other reinforcer has a strong effect. At times, exposure to one condition results in a similar response to a somewhat similar second condition. Implementing each condition for a relatively short period of time can help reduce these problems (O'Brien, 1968), as might clear separations between each treatment condition (such as introducing only one treatment condition per session).

Several procedures exist to help detect multiple treatment interference (Sidman, 1960). A simple phase change where one treatment condition is preceded by a baseline phase, when compared to another AB design containing the other treatment, and finally compared to an ATD combining both conditions, could be used to parse out the separate and interactive effects of the treatment conditions. Alternatively, the intensity of one treatment condition could be increased, with any subsequent changes in the following conditions (as compared to changes already witnessed in an ATD containing both conditions) attributable to carry-over effects.

Some additional caveats regarding proper use of the ATD are of note. First, although a baseline phase is not necessary in an ATD, inclusion of baseline data can be useful for both gathering further information on client functioning and interpreting the magnitude of treatment effects. If periodic baseline points can be included within the ATD itself, valuable information regarding background level, trend, and variability can also be gleaned, over and above what would be interpretable if treatment conditions alone were present.

Second, it is important to realize that although ATDs can effectively be used with four or even more treatment conditions and corresponding data series, an upper limit exists on the number of data series that can be meaningfully interpreted. One useful heuristic (Barlow, Hayes, & Nelson, 1984) is to count the number of data points that will likely be collected for the ATD's purpose and then divide this number by the desired number of data series. If several data points will be collected for each series, the clinician should be able to proceed as planned.

Third, the clinician must consider the amount of data overlap between data series when interpreting ATD results. Overlap refers to the duplication of level between series. Several issues must be considered if considerable overlap exists. First, the percentage of data points, relative to all data points in an involved series, that indeed overlap can be calculated. If this percentage is low, the likelihood of a differential effect is higher. Second, the stability of the measured behavior should be considered. If the frequency of a given behavior is known to vary widely over time, then some overlap on measures of that behavior between ATD conditions would be expected. Third, the clinician must note if any overlapping trends occur in the two conditions. If data in two series are similar not only in level but also in trend, then it seems plausible that a background variable, rather than the treatment conditions, might affect the data.

One final example is shown in Figure 8. These are the data from an airplane-phobic client in the study on the effect of cognitive coping on progress in desensitization (Hayes, Hussian, Turner, Anderson, & Grubb, 1983). Notice that there is a clear convergence as the two series progress. The orderliness of the data suggested that the results from cognitive coping were generalizing to the untreated scenes. Alternating a reminder not to use the coping statements with the usual statements then tested this possibility. The data once again diverged. When the original conditions were then reinstated, the data converged once more. This showed that the convergence was a form of systematic generalization, rather than a lack of difference between the two conditions. This is also a good example of the combination of design elements to answer specific questions. This particular design does not have a name, but it is a logical extension of design tools discussed above.

3.02.4.2.2 Simultaneous treatment design

Simultaneous treatment design (STD) is similar to ATD in which the two treatments are continuously present but are accessed by the choice of the subject. What is plotted is not the impact of the treatment but the degree to which it is accessed. In other words, an STD measures preference. As an example, suppose a clinician wished to assess the motivation of a disabled child for different kinds of sensory stimulation. Several kinds of toys that produced different sensory consequences could be placed in a room with the child and the percentage of time played with each kind of toy could be recorded and graphed. This would be an STD.

3.02.4.3 Combined-series Elements

Combined-series designs contain elements from both within- and between-series designs, and combine them into a new logical whole. Although many examples in the literature contain elements of both between- and within-series designs, true combined-series designs involve more than merely piecing components together. What distinguishes combined series elements from any combination of elements is that the combination yields analytical logic.

3.02.4.3.1 Multiple baseline

One of the more often encountered SCEDs is the multiple baseline. An adaptation of the simple phase change, the multiple baseline design allows control over some variables that often confound interpretation of within-series phase change data. Upon a phase change from baseline to treatment in a simple phase change, for example, the data would ideally indicate a sudden and very strong treatment effect. It would be arranged in such a way that background variability could be easily detected against the effects of the treatment. Even when this ideal outcome occurs, however, there is also the possibility that some extraneous variable having a strong effect on measured outcomes might co-occur with the onset of a treatment phase. Such an occurrence would have dire implications for interpretation of the simple phase change result. The multiple baseline design allows considerable control over such threats to validity.

Essentially, the multiple baseline typically involves a sort of simple phase change across at least three data series, such that the phase change between baseline and treatment occurs at different times in all three data series (Figure 9). The logic of the design is elegantly simple. Staggering the implementation of each respective phase change allows the effects of extraneous variables to be more readily observed. It is generally unlikely that any given extraneous occurrence will have an equal effect on phase changes occurring at three different points in time.

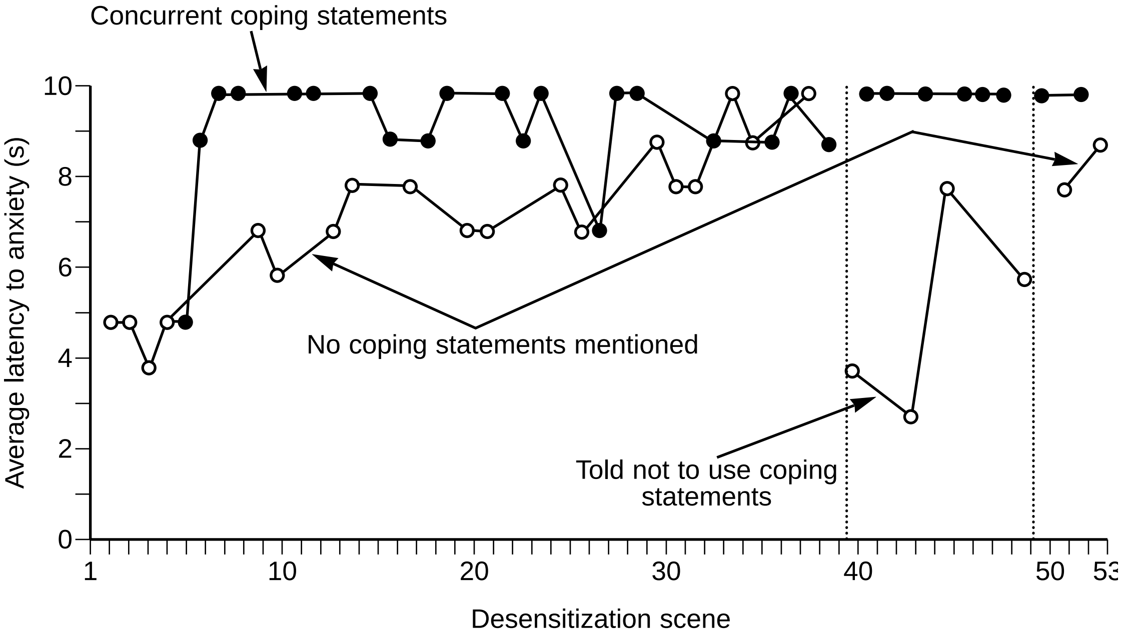

Figure 8 An example of series convergence in the ATD and its analysis by adding within-series components (redrawn from Hayes et al., 1983).

Implementation of a multiple baseline design greatly increases the potential number of comparisons that can be made between and within data series, ultimately strengthening the confidence with which conclusions are made from the data. Figure 3 details where such comparisons can be made. First, changes in level and trend within each data series (that is, between the baseline and treatment phase of each of the three data series) can be analyzed, just as with a simple AB design. Unlike a simple phase change, however, differences in level and trend between baseline and treatment can also be compared between three series of data. The design, in effect, contains replications of the phase change. If similar levels and trends are exhibited across all three series, the clinician can feel confident that the treatment is the most likely candidate for exerting the effect. Comparisons can also be made between the point of time at which the first phase change occurs, and the same points of time in the two remaining data series, where baseline data is still being collected. Such comparisons give the researcher information on whether some variable other than treatment might be responsible for observed changes. For example, a strong positive trend and marked change in level might be indicated by the data after the treatment phase is implemented. If similar changes occur in the other two data series at the same points in time, before treatment has even been implemented in those data series, it would seem clear that something besides treatment was exerting an influence on the data. A similar comparison can be made between the point at which the second phase change is implemented and the corresponding data points on the third series of data.

The type of data recorded in each of the three series must be similar enough so that comparisons can be made between the series, yet different enough that effects in one series are not expected from a phase change in another series. The context in which the data in each of the three series is collected can be of three varieties. The multiple baseline across behaviors requires that three relatively discrete and problematic behaviors, each of which might be expected to respond to a given treatment, be chosen. The treatment is then implemented in staggered, multiple baseline fashion for each behavior. The clinician would probably wish to choose behaviors that are unlikely to be subject to some generalization effect, so that a treatment implemented with behavior 1 results in concomitant change in one or both of the other behaviors (because, for example, the client begins to apply the principles learned immediately to those other behaviors). Such an effect would be easily observed in between-series comparisons (i.e., when a data trend in a condition where the intervention has not yet been initiated resembles the trend exhibited in an intervention condition, a generalization effect may very likely be present). However, the clinician could not be absolutely certain in such a case that the changes across behaviors were due to some generalization effect and not an extraneous variable. In

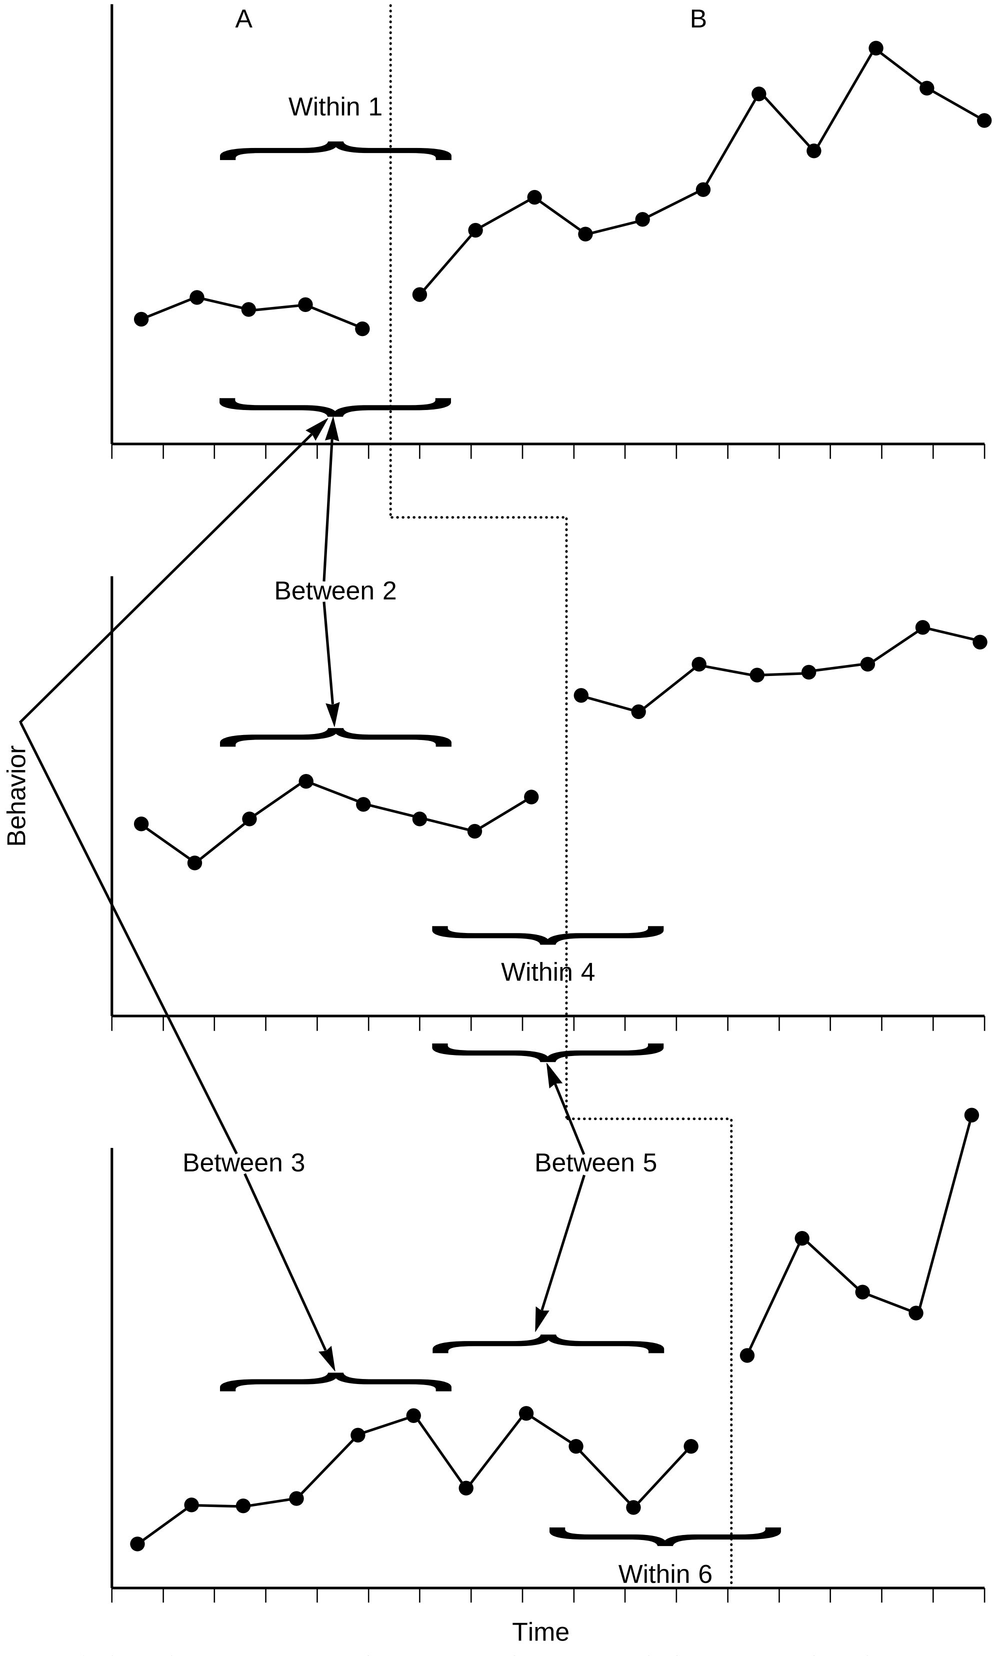

Figure 9 A hypothetical example of a multiple baseline, with between- and within-sources of data comparisons. Comparisons can be made between pre- and postphase change data within any of the three series, as well as between any two series at the points where an intervention is in place for one series and baseline conditions are still in effect for the second series.

general, if it seems theoretically likely that a generalization effect would occur under such circumstances, and no apparent confounding variable is present, then it is often safe to assume generalization occurred. Even if such an effect were observed, it might not be disastrous by any means. Implementing a treatment only to serendipitously find that it positively affects behaviors other than the targeted one could hardly be considered unfortunate.

An example of the multiple baseline across behaviors is provided by Trask-Tyler, Grossi, and Heward (1994). Developmentally disabled young adults were taught to use three cooking recipes of varying degrees of complexity (simple, trained, and complex), with the goal of the study being to determine whether or not specific skills would generalize across recipes. Simple tasks included preparing microwave popcorn while receiving specific instructions regarding its preparation. Trained tasks were analogs of previously taught simple tasks, where subjects used previously taught skills to prepare a different food (e.g., microwave french fries). Complex tasks consisted either of new tasks or novel combinations of previously trained tasks. Intervention phases were staggered across complexity levels, and occurred after a baseline phase where subjects completed recipes without instruction. Complexity level served as an appropriate analog for differing behaviors in this case, and the implementation of new phases were staggered with sufficient data points (i.e., three or over) occurring in each phase. The design use was also innovative in that it involved applied skills.

Alternately, the clinician may choose to implement a multiple baseline design across settings. If, for example, a client was socially withdrawn in a variety of circumstances (e.g., at work, at the gym, and on dates), social skills training might be implemented at different points in time across several of those circumstances. As another example, anger management training with an adolescent could be implemented in a staggered fashion at home, school, and at a part-time job site. As with the multiple baseline across behaviors, the clinician should be alert to the possibility of generalization effects.

An example of the multiple baseline across settings design is provided by Kennedy, Cushing, and Itkonen (1997; Figure 10). The study investigated the effects of an inclusion intervention on the frequency and quality of social contacts with nondisabled people, using two developmentally disabled children as subjects. The intervention included a number of components, such as placement in general school settings with nondisabled peers, and feedback. After a baseline where both subjects participated in special education classes only, the design took the shape of a multiple baseline across classes. One subject eventually participated in four classes, the other in two. Phase lengths were more than adequate (minimum of five data points), and phase changes were appropriately staggered (levels and trends stabilized before onset of the intervention in a new setting). The intervention was effective in increasing the frequency and quality of peer interactions.

Finally, a multiple baseline design can be implemented across persons. Such a manifestation of the design would, of course, require access to three clients with fairly similar presenting concerns subjected to the same treatment. As it is probably unlikely that anyone but a therapist at a university or health center would have simultaneous access to three such clients, it is acceptable to collect data on new clients as they present for services (Hayes, 1985). Objections exist to this approach (Harris and Jenson, 1985), but we feel strongly that the practicality of the approach and the control against extraneous factors that the design possesses greatly outweigh the potential risks.

The multiple baseline across persons design is exemplified by Kamps et al. (1992). The effects of social skills groups on the frequency of social skills interactions of high functioning autistic subjects with normal peers were analyzed across three subjects. Baseline consisted of frequency counts of social interactions before social skills training. Phase changes within each series did not occur until data stabilized, and phase changes across subjects were staggered approximately 10 sessions apart. A minimum of seven data points (usually more) were present in each phase. Social skills training had a positive effect on social interactions.

Ideally, phase changes should wait until the data indicates a clear level and trend, and is stable, before the phase change is executed. This is advisable when changing from baseline to treatment within a given series, and especially when executing staggered phase changes in the second and third data series. If no clear effect is observable in a series, then co-occurring data points between a series cannot be meaningfully interpreted.

An example of the multiple baseline is provided by Croce (1990). A multiple baseline across persons was used to evaluate the effects of an aerobic fitness program on three obese adults, while weekly body fat and cardiovascular fitness measurements were taken. Over three weeks of baseline data was collected in all subjects before treatment was delivered to the first subject. Treatment for the second subject was implemented three weeks after the first, and treatment for the third subject was delayed an

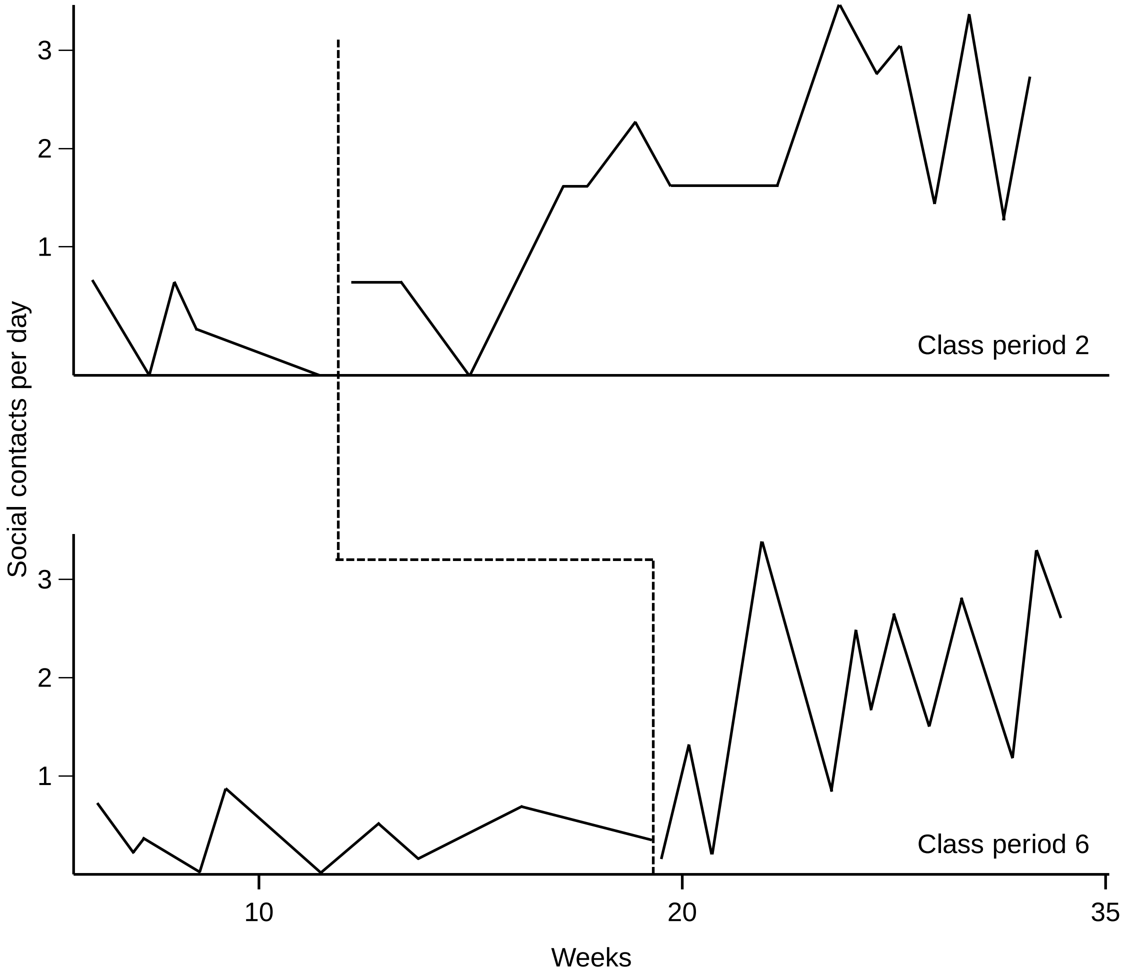

Figure 10 A multiple baseline across settings. Data was stable before phase changes in both settings, and comparisons between the settings indicate that the intervention was responsible for changes and that no generalization effect occurred (adapted from Kennedy et al., 1997).

additional three weeks. The data clearly indicated a desirable effect.

3.02.4.3.2 Crossover design

The crossover design essentially involves a modification of the multiple baseline allowing an additional degree of control over extraneous variables (Kazdin, 1980). It can be especially useful when only two (rather than three or even more) series of data can plausibly be gathered, as this added control tends to compensate for the control lost by the omission of a third series. This design has been widely used in pharmacological studies (Singh & Aman, 1981).

Execution of a crossover design simply involves simultaneous phase changes across two series of data such that, at any given point in time, opposite phases are in operation between each series. If series one's phase sequence was, for example, ABAB, a BABA sequence would be simultaneously delivered, with each phase change occurring at the same time in both series, and after treatment phases of precisely equal lengths. Such an arrangement can make even a relatively weak effect evident, as each treatment (B phase) always has a corresponding baseline (A phase) in the other data series to allow finer interpretations of stability, level, and trend.

3.02.4.3.3 Constant series control

One final combined series design warrants brief mention. A constant series control can be added to a series of data when baseline data alone is collected concurrently on some other person, problem, or situation of interest. In adding a constant series control to an in-school anger management intervention with a child, for example, relevant behavioral data might be collected at the child's home (where the treatment is not considered active) throughout the period where an ABAB phase sequence is being implemented at school. Treatment B effects from the school setting can then be compared to concurrently gathered baseline data from the home setting to assist in interpretation of the treatment's effects. Such a control is extremely useful when used in conjunction with a simple or complex phase change design.

A study by O'Reilly, Green, and Braunling-McMorrow (1990) provides an example of a baseline-only constant series control. O'Reilly et al. were attempting to change the accident-prone actions of brain-injured individuals. A written safety checklist that listed, but did not specifically prompt hazard remediation, was prepared for each of several areas of the home. If improvement was not maximal in a given area, individualized task analyses were prepared that prompted change in areas that still required mediation. The design used was a multiple baseline across settings (living room, kitchen, bedroom, and bathroom). Although phase changes from baseline to checklist prompts to task analysis occurred in staggered multiple baseline across the first three settings, a baseline condition remained in effect for the entire 29 weeks of the study. Results indicated very little evidence of generalization across responses, and the baseline-only constant series control provided additional evidence that training was responsible for the improvements that were seen.

3.02.5 FUTURE DIRECTIONS

Widespread use of SCEDs by practicing clinicians could provide a partial remedy to two currently omnipresent concerns in the mental health care delivery field: a virtual lack of use and production of psychotherapy outcome literature by clinicians, and the demand for demonstrated treatment efficacy by the managed care industry.

3.02.5.1 Potential for Research Production and Consumption by Practicing Clinicians

Line clinicians currently produce very little research. This is unfortunate since it is widely recognized that assessment of the field effectiveness of treatment technology is a critical and largely absent phase in the research enterprise (Strosahl, Hayes, Bergan, & Romano, in press).

Single-subject designs are well suited to answer many of the questions most important to a clinician. They are useful tools in keeping the clinician in touch with client progress and informing treatment decisions. Most of the requirements of these designs fit with the requirements of good clinical decision making and with the realities of the practice environment.

This has been true for some time, and the research production using these designs in the on-line practice environment is still limited. That may be about to change, however, for the reason discussed next.

3.02.5.2 Managed Health Care, Single-subject Design, and the Demonstration of Efficacy

The managed health care revolution currently underway in the USA represents a force that, in all likelihood, will soon encompass nearly all US mental health services delivery systems (Strosahl, 1994; Hayes et al., in press). The hallmark of managed care organizations (MCOs) is the provision of behavioral health services in a way that is directed, monitored, not merely compensated.

In generation I of the managed care revolution, cost savings accrued mostly to cost reduction strategies. That phase seems nearly complete. In generation II, cost savings are accruing to quality improvement strategies. Uppermost in this approach is the development of effective and efficient treatment approaches, and encouragement of their use through clinical practice guidelines.

Time-series designs are relevant to MCOs in three ways. First, they can allow much greater accountability. Single-subject designs provide an excellent opportunity for the clinician to document client progress and provide sufficient justification to MCOs, HMOs, and PPOs for implementing treatments or treatment components. Even a simple AB is a big step forward in that area. Second, when cases are complex or treatment resistant, these designs provide a way of evaluating clinical innovation that might be useful for improving the quality of treatment for other cases not now covered by empirically supported treatments. Finally, these designs can be used to evaluate the impact of existing treatment programs developed by MCOs.

3.02.6 CONCLUSION

This chapter provides a brief overview of current single-subject design methodologies and their use in the applied environment. The design elements are a set of clinical tools that are effective both in maximally informing treatment decisions and generating and evaluating research hypotheses. Single-subject designs fill a vital role in linking clinical practice to clinical science. With the evolution of managed care, this link is now of significant economic importance to a major sector of our economy.

3.03.1 INTRODUCTION

A major function of clinical psychology is to provide treatment or other interventions for clients who suffer from mental illness or seek relief from problems. This chapter addresses the role of experimental evaluation of treatments as a source of data in deciding about the utility of a treatment. In the medical literature, such studies are referred to as randomized clinical trials (RCTs) (Pocock, 1983) and many recent studies of psychological treatments also use this terminology (e.g., Bickel, Amass, Higgins, Badger, & Esch, 1997). This chapter will consider the strengths and weaknesses of a number of strategies for judging treatment utility; review some historical background of the experimental study of treatment; examine the experimental designs that have been used to study psychological treatments and the circumstances under which such experiments are appropriate. In each of the sections regarding specific experimental designs, exemplar studies will be discussed in some detail in order to highlight relevant issues for evaluating the literature and for the design of future studies.

3.03.2 COMPARING STRATEGIES FOR TREATMENT EVALUATION

In order to set the experimental study of treatment into context, this section will review a variety of strategies for evaluation of treatment efficacy attending to their strengths and weaknesses.

3.03.2.1 Case Reports and Summaries of Case Series

This strategy represents perhaps the method with the longest history. For example, Brill (1938) cites a case treated in 1880 by Josef Breuer (cf p. 7) of a young girl with symptoms of "paralyses with contractures, inhibitions and states of psychic confusion." Under hypnosis she was able to describe the connections between her symptoms and past experiences and "... by this simple method he freed her of her symptoms." Another case described by Brill concerns a four-year-old child who became nervous, refused to eat, and had frequent crying spells and tantrums. The symptoms began shortly after the mother was separated from the child and she was "cured" soon after the mother returned. The mechanism that was posited to account for the effect was a disturbance in libido.

Much more recently, *Consumer Reports* (1994, 1995) report the results of a survey of 4000 subscribers who reported their experiences with psychotherapy broadly defined. Respondents to the survey reported in general that they had benefitted from their psychotherapy and, of particular interest, that more and longer psychotherapy was associated with greater benefit. This survey has been reviewed and received careful critique by psychologists (Brock, Green, Reich, & Evans, 1996; Hunt, 1996; Kotkin, Daviet, & Gurin, 1996; Kriegman, 1996; Mintz, Drake, & Crits-Christoph, 1996; Seligman, 1995, 1996).

These examples differ in a number of ways. The most obvious is that they span over a century. The more relevant one for the present purpose is that the *Consumer Reports* survey carries the weight of numbers and implied authority as a result. However, both single case reports and reports that summarize large numbers of cases share limitations. Neither can address the very compelling question regarding the reported outcomes—"compared to what?" In the *Consumer Reports* survey, there are a number of obvious hypotheses that can be entertained regarding the absent comparison groups that call into question the validity of the reported finding. The finding that psychotherapy was helpful could be because those who did not feel they had benefitted from their psychotherapy did not respond to the questionnaire. The finding that longer psychotherapy was more helpful could be because those who experienced benefit continued in treatment longer or because those who discontinued early needed to justify their discontinuation. Statistical modeling of alternative causal interpretations cannot fully exclude these interpretations. The common characteristic of both the attributed interpretations of findings from case reports or case series and the criticism of them is that there is no formal procedure for judging the accuracy of the interpretation.

Such reports serve the important function of generating hypotheses regarding treatments and interventions that can lead to well-designed studies. But they are not designed to test hypotheses and therefore cannot provide definitive evidence for treatment efficacy.

3.03.2.2 Single Case Experimental Designs

Chapter 2, this volume, on single case designs, discusses the methodologies for assessing causal relationships in individuals. A striking advantage of single case designs is that they can be used to evaluate treatments for individuals with very specifically defined characteristics. These characteristics do not need to be shared with large numbers of other patients or clients for the experiments to be valid. The applicability of the specific interventions studied to broader populations of clients will, of course, depend on the similarity of such clients to the subjects studied. An important disadvantage of single case designs is that they are only applicable in conditions in which return of the target complaints can be reliably demonstrated once the treatment has been removed. If a treatment results (or is hypothesized to result) in a change in personality or in the orientation of an individual to himself or others, then the repeated administration and withdrawal of treatment that is the hallmark of single case designs will not provide useful information. A further disadvantage is that the comparisons are all internally generated and generalization is accomplished only through assessment of multiple cases with similar individual characteristics and treatment.

3.03.2.3 Quasi-experimental Designs

These methods, described in detail in Chapter 4, this volume, take advantage of naturalistic treatment assignment or self-selection and use statistical methods to model outcome and to provide controls for the major limitation of these methods—namely that assignment to treatment is not random. A further advantage is that evaluation of treatment outcome can be independent of treatment delivery (and even blind to the knowledge of treatment) so that the effects of expectancy on outcome are controlled. The major weakness of such designs is that the biases of treatment selection are allowed full rein.

3.03.2.4 Randomized Experimental Designs

Randomization is the hallmark of these studies. Random assignment to intervention provides the potential to control for biases that treatment self-selection and choice introduce into the evaluation of treatment outcome. The disadvantages that randomized treatment studies have include the logistical difficulties in implementation and restrictions in generalizability. Generalizability is restricted to clients who are willing to consider randomization. Individuals who come to treatment facilities with a strong preference or expectation may well reject randomization to treatment as an option and insofar as matching to treatment influences outcome, the absence of such subjects reduces generalization. Subject refusal to participate, particularly if it occurs after treatment assignment is known, can further compromise the advantage that random assignment introduces. Refusal after treatment assignment is known implies that subjects whose expectations are met continue and that those who did not get the treatment they preferred have chosen not to participate. If such refusal is frequent, the principle of randomization has been compromised and interpretation of findings will encounter limitations similar to those described for quasi-experimental designs. Attrition from all causes may introduce bias (Flick, 1988). Despite these disadvantages, randomization offers insurance that, within the population studied, bias—particularly from unknown sources, has been contained. Randomized experimental studies share with quasi-experimental designs the potential advantages afforded by the separation of evaluation of outcome from provision of the intervention.

3.03.3 HISTORICAL BACKGROUND

Early research in psychotherapy ran on two relatively independent tracks: the first emphasized the internal process of the psychotherapeutic encounter; the second was concerned with evaluating the effects of psychotherapy *per se*. In the latter studies the primary comparisons were between patients or clients who received psychotherapy and those who did not. Most controls centered around controls for treatment time such as deferred entry into treatment using waiting lists. In these experimental studies, attention to the content of the psychotherapy was descriptive. This position was strongly bolstered by the writings of theorists such as Frank (1971), who held that general constructs such as positive regard and the therapeutic alliance underlay the effects of psychotherapy.

Smith and Glass (1977) revolutionized the field with the publication of the first meta-analysis of the psychotherapy literature, demonstrating a moderate effect size for the comparison between psychotherapy and no treatment (see Chapter 15, this volume, for a discussion of current meta-analytic methods). At the same time, increased attention to measurement of change in psychotherapy (Waskow & Parloff, 1975) and the development of manualized treatments (see Chapter 9, this volume) signaled a change in the models that were available for the study of psychological treatments.

During the same period, attention to methodology in clinical psychology quickened (Campbell & Stanley, 1963, 1966; Cook & Campbell, 1979). The emergence of medications for the treatment of mental illness had inaugurated experimental studies of these treatments using rigorous designs drawn initially from clinical psychology that included randomization, double-blind administration of medication, placebo controls, diagnostic specificity, rating scales that paid attention to specific signs and symptoms of psychopathology (see Prien & Robinson, 1994, for a recent review of progress in methods for psychopharmacology). The demand for similar studies of psychological interventions became apparent. The modern era of experimental studies of psychotherapy and other psychological interventions was upon us.

3.03.4 APPROPRIATE CONDITIONS FOR RANDOMIZED GROUP DESIGNS

Experimentation is best suited to address comparative questions that would be biased if the groups being compared were self-selected. Random assignment of individuals to groups controls for biases introduced by self-selection. Some questions—for example, those regarding differences between young and old people or men and women—obviously will not be addressed experimentally, although later in the chapter the question of designs to study individual differences in relation to an experimental condition will be considered.

Some examples: does marital therapy prevent divorce?; is cognitive-behavior therapy helpful in depression?; does family psychoeducation potentiate the effects of medication in schizophrenia?; should children with attention deficit disorder receive medication or family support?; does respite care for Alzheimer's patients reduce physical illness in caregivers?; does medication reduce craving in alcohol dependent individuals? In all these examples, an intervention is either contrasted to others or in the cases where no comparison is stated, it is implied that the comparison is with a group that does not receive an alternate intervention.

The hallmark of all these questions is that they identify a group or condition and ask about an intervention. The implication is that the findings from the experiment will apply to members of the group who did not receive the intervention in the experimental study. This assumption represents a statistical assumption—it is required for the use of virtually all statistical tests applied in evaluating the questions under review. It also represents an important clinical concern. Experiments are not conducted solely for the benefit of the subjects who participate in the research. It is anticipated that the conclusions will be applicable to other individuals who share characteristics (ideally key characteristics) with those who were subjects in the research.

Perhaps the greatest threat to the validity of experimental studies is that there is something that distinguishes the members of the group (depressed patients, children with attention deficit disorder) who agree to randomization from those who will not participate in a study of randomized treatment. In the general medical clinical trials literature where the conditions to be treated are defined by readily measurable signs and symptoms or by physiological measurements (e.g., tumor size), that assumption is readily accepted and is therefore generally untested. In the psychological literature the question may be considered but there are very few studies that have actually drawn a sample of subjects from a population in order to know whether the subjects of a study are like the population from which they came. In other words, although we look to randomization as a control for bias in evaluating the effect of a treatment or intervention, there has been little attention paid to whether subjects who agree to randomization represent a bias that is negligible or substantial.

3.03.4.1 Ethical Requirements

Certain ethical conditions regarding the subjects and the treatments or interventions must be met (Department of Health and Human Services, 1994). Research participation requires informed consent from the participant or from an appropriately authorized surrogate, for example, a parent for a minor child. Even in cases where consent is obtained from a surrogate, the research participant (e.g., the child) must provide "assent." Assent is the term used for agreement to participate by individuals who are judged to lack the capacity to provide fully informed consent. Currently in the USA regulations are promulgated by the Department of Health and Human Services that define 12 elements of informed consent. They are:

(i) An explanation of the procedures to be followed, including specification of those that are experimental.

(ii) A description of the reasonably foreseeable attendant discomforts and risks and a statement of the uncertainty of the anticipated risks due to the inherent nature of the research process.

(iii) A description of the benefits that may be expected.

(iv) A disclosure of appropriate and available alternate procedures that might be advantageous for the subject.

(v) An offer to answer any inquiries concerning the procedures.

(vi) A statement that information may be withheld from the subject in certain cases when the investigator believes that full disclosure may be detrimental to the subject or fatal to the study design (provided, however, that the Institutional Review Board (IRB) has given proper approval to such withholding of information).

(vii) A disclosure of the probability that the subject may be given a placebo at some time during the course of the research study if placebo is to be utilized in the study.

(viii) An explanation in lay terms of the probability that the subject may be placed in one or another treatment group if randomization is a part of the study design.

(ix) An instruction that the subject may withdraw consent and may discontinue participation in the study at any time.

(x) An explanation that there is no penalty for not participating in or withdrawng from the study once the project has been initiated.

(xi) A statement that the investigator will inform the subject of any significant new information arising from the experiment or other ongoing experiments which may bear on the subject's choice to remain in the study.

(xii) A statement that the investigator will provide a review of the nature and results of the study to subjects who request such information.

All these essential elements must be included in an Informed Consent Form to insure adequate consent to participate in any research.

In studies that involve randomization to treatment, some elements are of particular importance because they represent concepts that are sometimes difficult for potential subjects to appreciate. The first, of course, is that of randomization itself—that treatment will be decided "as if tossing a coin." The second is that the clinician or treater will not choose "the best" treatment for the client. Other elements of informed consent that need to be emphasized for a truly informed process is that the subject is free to withdraw at any time and that those providing treatment may also discontinue the subject's participation if they believe it to be in the subject's best interest.

In most countries research involving human subjects must be reviewed by local Research Ethics Committees or IRBs that are mandated to insure that the research meets ethical standards, that all elements of informed consent are present, and that the interests of subjects are protected.

A number of issues regarding consent that go beyond the 12 critical items are currently a subject of debate. Participants in these deliberations include various regulatory bodies, independent commissions, and private individuals and groups that are self-declared protectors of those who may participate in experiments regarding treatments or interventions of interest to clinical psychology. Among these issues are the following: requiring that an independent person unaffiliated with a given research project oversee the consent process; expanding the definition of those who lack the capacity to provide informed consent to include populations such as all those diagnosed with schizophrenia and other illnesses; restricting the conduct of research that does not offer direct benefit to the participant subjects; elimination of the use of placebo treatment conditions in patient groups for whom there is any evidence of treatments that are effective. These potential changes may well alter the nature of experimental research regarding treatment and intervention.

In general, concerns about placebo treatment or no-treatment control conditions have been hotly debated in the arena of pharmacological treatment rather than psychological interventions. However, as evidence regarding the efficacy and effectiveness of psychological interventions becomes widely accepted, experimental strategies such as waiting list controls, "usual care," and even nonspecified psychotherapies may require re-evaluation. One strategy that may receive increasing attention and popularity is that of treatment dosage. In other words, a comparison group may be defined as one that receives the intervention of interest but receives less of it.

Interventions and control conditions being compared should be potentially effective; there should be evidence regarding benefit. If this assertion is accepted, how can a "no-treatment" comparison group be included in an experiment? First, there should be provision for the subject to receive the potentially more effective intervention following study participation. In other words, the "no-treatment" group is really a delayed treatment or the time hallowed waiting list condition. This may be relatively easy to implement with short-term treatment interventions but more difficult for long-term interventions. Alternate solutions include the use of minimal treatment conditions. Later in the chapter, both of these conditions will be discussed in more detail from the substantive perspective. In the present context, both represent plausible solutions to the ethical dilemma of providing appropriate treatment for client populations for whom there exist a corpus of information regarding treatment effects. Obviously, these concerns are moot in specific patient or client populations where there are no data regarding treatment effects. The ethical dilemma is heightened when the intervention is long term or there may be substantial risk if treatment is deferred. For example, studies of treatment for depression generally exclude subjects who are suicidal.

3.03.4.2 Stage of Treatment Development

The ideal sequence of treatment development includes the following stages: innovation; preliminary description in practice, usually by the innovators or developers of the treatment; comparative experimental studies to determine treatment efficacy and investigate client characteristics that may be linked to treatment response; dissemination into clinical practice; and evaluation of outcome under conditions of usual clinical care. Experimental, randomized designs may take several forms during the sequence outlined. The first is often a study that compares the new treatment with no treatment. As indicated earlier, that condition is most likely to be defined by a waiting list condition or deferred treatment. Other studies that provide comparisons to other established treatments may follow. At the present time, studies that examine psychological interventions in relationship to medication are often carried out. These studies may address direct comparative questions regarding medication and a psychological intervention or they may address relatively complex questions regarding the additive or interactive effects of medication and a psychological intervention.

3.03.4.3 Treatment Specification: Definition of Independent Variables

As indicated above, randomized designs are most valuable when the interventions can be well-specified or defined. Since the goal of such research is generalization, the advantage of well-specified treatment interventions is that their reproduction by other clinicians is possible. Manuals such as those discussed in Chapter 9, this volume, represent the ideal model of treatment specification, but other methods can be considered. The training of the treatment provider can provide a plausible statement regarding specification. For example, clinical psychologists with a Ph.D. who are board certified and who have completed an established training course may represent an appropriate statement regarding a treatment specification.

Specification should also include such elements as treatment duration, frequency, and number of contacts. Duration and number may appear to be relatively simple constructs but in examining psychological interventions the duration of treatment may not be rigidly defined. In some cases, treatment adherence by clients will affect duration, frequency, and number. In other circumstances, treatment may be continued until a specified outcome is reached. Under these conditions, duration of treatment until a criterion of improvement is reached may represent an outcome itself.

Finally, the most careful specification needs to be matched by measurement of adherence to the specified treatment. Did therapists do what they were supposed to do? This represents an interesting shift in research on interventions. Earlier in the history of psychotherapy research, when the emphasis was on the process of psychotherapy, the evaluation of what happened during the psychotherapeutic encounter was of interest because it was assumed that psychotherapeutic interventions altered outcomes. One could draw an analogy to recording the practices of a gifted cook in order to ascertain the recipe. As the emphasis has shifted to the evaluation of outcomes, the interest in the nature of the interpersonal interactions that comprise the intervention has come to be seen as assurance of adherence or "fidelity" (Hollon, Waskow, Evans, & Lowery, 1984). The question now is to determine whether a given cook has followed the recipe.

3.03.4.4 Client/Subject Characteristics

Characterization of the clients in the randomized trial provides the means for communicating attributes of the population of clients who may be appropriate for the treatment in routine clinical practice. Currently, the most common strategy for characterizing clients is the use of diagnostic criteria that provide decision rules for determining whether clients fit categories. The most widely used are those of the World Health Organization's *International classification of diseases* (World Health Organization, 1992) and the American Psychiatric Association's *Diagnostic and statistical manual of mental disorders* (American Psychiatric Association, 1987, 1994). The use of specified diagnostic criteria (and even standardized instruments for ascertaining diagnosis) provides some insurance that clients participating in a given study share characteristics with those who have been participants in other studies and with potential clients who may receive the treatment at a later time. However, under some circumstances it may be preferable to specify client inclusion based on other methods—such as the reason for seeking clinical assistance rather than a formal clinical diagnosis. An advantage of using inclusion criteria other than diagnosis is that problem-focused inclusion criteria may make translation of findings from a randomized trial to clinical practice easier.

A second issue regarding client characteristics in randomized studies is insuring that important client characteristics which may influence outcome are balanced across treatment groups. One strategy is to conduct relatively large studies. Randomization is designed to minimize imbalance but, as anyone who has seen heads come up 10 times in a row knows, in the short term randomization may well result in imbalance. One of the most common ways to achieve balanced groups is to randomize to treatment or condition within a prespecified group; for example, gender or age to insure against the possibility that by chance disproportionate numbers of one group are randomized to one treatment condition. A second strategy is to use an adaptive randomization algorithm (Pocock & Simon, 1975; White & Freedman, 1978). In this method, several client characteristics that are known or hypothesized to affect the outcomes of interest in the study are identified. The goal of the randomization algorithm is to insure that the groups are relatively well balanced considering all of the characteristics simultaneously. A particular algorithm may specify a number of characteristics but when the number exceeds three or four, the overall balance is unlikely to be affected. The characteristics can also be weighted so that some are more likely to influence treatment assignment than others. Adaptive randomization is a dynamic process in which subject characteristics are fed into a program that generates a treatment assignment such that the identified characteristics will be well balanced across all groups.

What is central to randomization within groups or adaptive randomization is the premise that the chosen characteristics are known or hypothesized to affect the outcomes of interest in the study. Characteristics that are not expected to influence outcome do not need to be considered in this way. Section 3.03.6 discusses the use of individual differences among study participants in attempting to understand outcome differences among treatments or interventions.

3.03.4.5 Specification and Assessment of Outcome: Definition of Dependent Variables

To state the obvious, outcome criteria should reflect the intended effect of the interventions studied and the reliability and validity of the assessment instruments used should be established. In general, there are advantages to using some measures that are established in the field. This provides the opportunity to compare findings across studies and aids in the cumulative development of knowledge (Waskow & Parloff, 1975). In addition, it is valuable to include study-specific measures that focus on the particular intervention(s) under investigation and hypotheses being tested. In discussing examples of specific studies in later sections of this chapter, the issue of whether differences were found on standard measures or on measures that were idiosyncratic to the study in question will be considered.

Also of relevance is who assesses outcome. In pharmacologic clinical trials, double-blind procedures represent standard operating procedure. Concerns are often expressed that side effect patterns and other "clues" may serve to break the blind, but blinding preserves a measure of uncertainty regarding treatment assignment (Cole, 1968). In studies of psychological intervention, double-blind conditions are not possible. The subject and the treating clinician know what treatment the subject is receiving and commitment and enthusiasm for treatment are assumed to be present. For this reason, a common strategy is to include independent assessors. It is not a perfect strategy. Such assessors have only limited opportunity to observe subjects and may not be sensitive to subtle but important cues because of their limited contact with the subjects. In this context, both initial training of assessors to insure reliability and ongoing monitoring of reliability are critical.

3.03.4.6 Study Duration

Study duration includes two components: duration of the intervention and duration of postintervention evaluation. Duration of the intervention should be theoretically driven, based on the nature of the clinical problem that is being addressed and the mechanism of action of the intervention. Short-term interventions are much easier to investigate, particularly short-term interventions for which manuals have been developed. It appears that manuals are easier to develop for short-term interventions. However, some questions will require longer-term intervention. Interventions whose duration are reckoned in months rather than weeks require additional care to avoid subject attrition and to insure that the treatment remains constant during the long period of time that it is being delivered.

Post-treatment evaluation or follow-up after treatment ends is common in studies of psychological interventions and addresses the important question of whether effects persist in the absence of continued treatment intervention. Such follow-up studies are subject to the criticism that uncontrolled interventions may have occurred during the post-treatment period and may bias the outcome. But, if an intervention is hypothesized to exert a long-lasting effect that may include change in personality or long-term functioning, such evaluation is required. Follow-up evaluations are also subject to increased problems of attrition and the risk that differential attrition may introduce bias. Comparisons of baseline and demographic characteristics are frequently made between those subjects who are ascertained at the end of follow-up and those who are lost. This provides some measure of comfort, but further important comparisons should include treatment group and measures of outcome at the completion of study treatment. An incorrect strategy that has fallen into disuse was to compare those not ascertained with the full cohort, including those lost to follow-up, so that those not ascertained were included in both groups.

In studies of pharmacologic treatment, reversal of effects on discontinuation of treatment has been taken as *prima facie* evidence of efficacy. In fact, a major research design strategy in psychopharmacology is to establish efficacy of treatment in a cohort and then to randomize subjects to continuation or discontinuation of medication. Differential levels of symptom severity after a fixed experimental period and time to symptom exacerbation are taken as evidence of treatment efficacy. In contrast, studies of psychological interventions have often considered persistence of effect following the end of treatment as evidence for the efficacy of the psychological intervention. The problem that these conflicting paradigms represent will be considered further in Section 3.03.5.3 which considers comparative effects of pharmacologic and psychological treatments.

3.03.5 STUDY DESIGNS

The choice of study design always involves compromise. The clever experimenter can always think of additional controls and variations. In the previous section some of the relevant issues have been highlighted. Ethical considerations may proscribe some scientifically appropriate conditions. For example, under some circumstances deferring treatment through the use of a "waiting list" control may be inappropriate. Financial resources may constrain designs. Aside from funding constraints, availability of appropriate subjects may limit the number of conditions that can be studied. This may be stating the obvious, but the more conditions and the larger the number of subjects in a study, the longer it will take to complete the study and the longer an important clinical question will remain unanswered. Each additional group in a study increases both the cost and the duration of a study. Finally, there is no single, ideal design. Ultimately, the design of a clinical experiment represents a decision that is driven by the hypotheses that are under investigation. What is critical is the recognition by the investigator (and by the reader/critic of the research) of the hypotheses that can be tested, and conversely, the questions that are simply not addressed by a given study.

3.03.5.1 Simple Two-group Comparisons

Designs involving only two groups are often used in the early stages of research with a given form of psychotherapy. The comparison group may be a no-treatment waiting list for the duration of the treatment, treatment "as usual" in the treatment setting, or a nonspecific psychological intervention. Nonspecific psychological interventions are sometimes referred to as "placebo" treatment in the literature. Comparisons of two specific psychological interventions also represent potential two-group comparisons. A final model may include a treatment and no-treatment comparison in the presence of a specified medication condition (see Section 3.03.5.3 for discussion of this design in the context of other designs that include medication conditions).

Such studies may evaluate the benefit of two specific psychological interventions, of a specific intervention vs. a nonspecific control (usual care) or of intervention vs. none. The hypotheses and specific clinical questions that drive a given investigation should, in principle, drive the particular nature of the experimental and control groups. However, sometimes logistic considerations such as the nature of the treatment setting and the treatments that are routinely provided in the setting may influence the design of the experiment. A further, important factor may be the clinical needs of the clients and the urgency of providing some intervention.

There are limitations of two-group designs. Whatever the outcome, the design will not allow testing of a range of alternate hypotheses. If the study does not include a no-treatment control group, there is no control for time, spontaneous remission, or improvement. If the study does not include an alternate intervention group there is no control for nonspecific factors in treatment or for the specific characteristics of the designated experimental treatment. Further, if the study includes two specified interventions, there is no control for either receipt of any treatment or for nonspecific factors in treatment.

Interpretation of the findings from two-group studies absent a no-treatment control is difficult if there are no differences in outcome between the groups. No difference can be interpreted as Lewis Carroll and the Red Queen would have us believe "that all have won and all shall have prizes" or that there is no effect of either. Interpretation of studies that do not include a no-treatment group may often depend on integrating findings from other prior studies that did include such controls—not necessarily a bad state of affairs. As the field of experimental studies of psychological interventions matures, it may become less appropriate to implement studies with no-treatment control groups.

In the following example of a two group design, Keane, Fairbank, Caddell, and Zimering (1989) compared implosive (flooding) therapy to a waiting list control in 24 subjects with post-traumatic stress disorder (PTSD). Interestingly, the study design had originally included a stress management group, but for unspecified reasons, this condition was not successfully implemented, and those subjects are not included in the report. Thus, the two-group comparison is between a specified treatment and a no-treatment control. Implosive therapy was manual driven, following a manual (Lyons and Keane, as cited in Keane et al., 1989), and included between 14 and 16 sessions. The experimental group received baseline, post-treatment (elapsed time from baseline not reported), and a six-month follow-up assessment. The wait-list control group was assessed twice: at baseline prior to randomization and after, on average, four months. Half of the implosive therapy group and the majority of subjects in the wait-list group received anxiolytic medication because of, as the authors note, "... concerns about placebo groups and no treatment controls ... we didn't attempt to withdraw these patients from the medications which were prescribed to them" (Keane et al., 1989, p. 249). The authors maintain that the comparison of implosive therapy to subjects who were receiving pharmacotherapy (even if it was not systematically administered) represented a more stringent test of implosive therapy—although it was not a part of the original design. Subjects were assessed using well-known standardized assessments scales for depression, trait and state anxiety, and instruments specifically designed by the investigators for the assessment of PTSD. Post-test assessments were completed by the therapist who treated the subject in the implosive therapy group and by one of the same therapists for the wait-list group. In addition, the subjects rated themselves on depression, anxiety, and satisfaction with social adjustment in several life areas.

Implosive therapy appeared to improve depression and anxiety according to self-report and specific features of PTSD as rated by the therapists. No changes in social adjustment were seen.

Strengths of the study include randomization, specification of diagnosis, apparent absence of dropouts in both conditions, the existence of a manual for the experimental treatment, and the use of both standard outcome measures and measures tailored to the specific study hypotheses. Although subjects were randomly assigned to treatment, the randomization was compromised by the fact that treatment in one of three groups to which subjects were randomized was, for unspecified reasons, not fully implemented. In other words, this study was a two-group design in execution rather than intent. Another weakness is that assessments were completed by the therapists who treated the subjects and who therefore knew the treatment assignment. As discussed in Section 3.03.4.5, when treatment assignment is known, there is a potential bias.

3.03.5.2 Multiple-group Comparisons

Multiple-group comparisons offer the opportunity to test hypotheses simultaneously regarding comparisons of interventions (specificity of effects) and of intervention to a no-intervention control. If the interventions being studied derive from theoretical models, their comparison may test specific hypotheses regarding the psychological mechanisms that underlie the condition being treated. Other more pragmatic questions that can be addressed in multiple-group comparisons include group vs. individual contact and treatment intensity. However, it should be noted that when intensity or dosage of the intervention becomes a condition, control for amount of contact is lost. Again, there is no single "best" design. The appropriate design depends on the questions being asked and the appropriate questions depend on the stage of research. For example, questions of treatment duration or frequency are more likely to be asked after a particular treatment has been shown to have an effect.

Brown and Lewinsohn (1984) compared three psychoeducational approaches in treating depression that all used the same course materials: class, individual tutoring, brief telephone contact, and a delayed treatment control. Sixty-three individuals who met diagnostic criteria for unipolar depression and paid a course fee were randomly assigned to one of the four groups. Half the course fee was refunded if subjects completed all evaluations. Subjects in the three immediate treatment groups were assessed pre- and post-treatment and at two later follow-up points. The delayed treatment control group was assessed at baseline and at eight weeks, the time equivalent of post-treatment after which they received the class condition. All treatments focused on specific behaviors believed to be dysfunctional in depression (although not necessarily in the study subjects) and followed a syllabus that included a text (Lewinsohn, Munoz, Youngren, & Zeiss, 1978) and a workbook (Brown & Lewinsohn, 1984). An independent interviewer completed a standardized diagnostic assessment at baseline and of symptoms at later assessment points. Subjects completed three standardized self-report measures. The primary outcome measure was a factor-analytically derived score that included all three self-report measures.

Improvement was seen in all three immediate treatment groups on this single composite measure compared to the delayed treatment group. There were no differences among the active treatment groups either in self-report or in rate of diagnosed depression at follow-up. Comparison of high and low responders to treatment found few differences; none were a function of specific treatment. No detailed assessment of psychopathology or self-report measures was made.

The strengths of the study include randomization, a design that tested specific effects of a treatment modality and the method of delivery, the absence of drop-outs from treatment or assessment, specification of treatment conditions, the use of standardized measures of outcome assessment, and the use of independent assessors. The major weakness of the study is not in its design but the limited use made of the assessment battery. Ratings made by the independent assessors were only used to assess the presence or absence of diagnosable depression at the six-month follow-up and the use of a single summary score for all self-report measures may well conceal more than it reveals. A second weakness is the absence of assessments of implementation—how well the instructors used the course materials in the three conditions and whether all three conditions were implemented equally well.

It is difficult to decide whether charging subjects for treatment is a strength or a weakness. On the one hand, payment for treatment is characteristic of clinical treatment settings. All subjects completed the study and it could be argued that motivation to receive a 50% rebate on the course fee was a factor in enhancing study completion. On the other hand, the authors report that one of the major reasons that screened potential participants did not enter the study was inability to pay. Thus, the study population may have been biased by the exclusion of these subjects.

This study exemplifies a model that deconstructs a psychotherapeutic approach—in this case a psychoeducational approach to the treatment of depression—in order to identify which treatment delivery strategy offers advantages in outcome given that the strategies differ in the amount of clinical time and resources required to deliver the treatment. All subjects, including the delayed treatment group, reported significant improvement. The implication of these findings is that the least costly method of treatment delivery, brief telephone contact, should be implemented. However, there was no report regarding the acceptability of the method of treatment delivery and as noted earlier, there was no assessment of post-treatment symptoms. In the absence of these data, perhaps a firm clinical recommendation is premature.

3.03.5.3 Multiple-group Comparisons that Include Medication Conditions

Although in principle, designs that compare medication to psychological interventions can be classified in terms of whether they are simple comparisons (Section 3.03.5.1), multiple comparisons (Section 3.03.5.2) or represent factorial designs (Section 3.03.5.4), they entail unique research challenges and therefore merit separate consideration. The first design challenge was introduced earlier, namely the difference in the model of assessing effects. Follow-up assessments after treatment ends are seen as important sources of information in studies of psychological treatments. In contrast, such assessments are rare in studies of pharmacotherapy. Relapse or re-emergence of symptoms after treatment discontinuation is taken as evidence of efficacy. Therefore, discontinuation designs to study efficacy of treatment are common in psychopharmacology. A second design challenge is whether psychological and pharmacologic treatments should be introduced at the same time or are appropriate for different stages of an illness. Third, pharmacologic studies use double-blind methods as the preferred strategy to control assessor bias and therefore studies often rely on treating clinicians to assess outcome. Because it is not possible to blind treating clinicians to the psychological treatment they are providing, studies of psychological interventions rely on independent assessors who, although they will be blind to treatment assignment, have reduced opportunity to observe, and have minimal opportunity to develop rapport with the subjects they are assessing. For these reasons, evaluations by independent assessors may be less sensitive than those made by treating clinicans. Fourth, psychological interventions are often hypothesized to affect different aspects of outcome than pharmacologic interventions, so that direct comparisons of effects may be difficult.

Historically, pharmacologic clinical trials have relied more heavily on medical diagnoses of mental illness than studies of psychological interventions. But current research in both pharmacologic and psychological treatment is largely wedded to specific diagnoses derived from the *DSM* of the American Psychiatric Association (1987, 1994) or the *ICD* of the World Health Organization (1992). Parenthetically, one can question whether the increased reliance on medical diagnostic schemes such as *DSM* and *ICD* represents an advance in studies of psychological intervention. It has been argued that diagnostic specificity enhances reliability and therefore enhances replication and communication. On the other hand, clients who seek treatment do not necessarily seek help for a specific diagnostic label.

A wide range of designs have been used to examine the relationship of medications and psychological treatments. In the simplest, a medication or placebo is added to a uniform psychological intervention, or the converse, a psychological intervention or control condition is added to an established medication condition. These designs examine the additive effect of the modality that is superimposed. Questions like does naltrexone enhance abstinence in alcoholic subjects who are in a therapeutic milieu or does social skills training enhance social functioning in schizophrenic subjects who are maintained on antipsychotic medication can be addressed in this manner. The major design challenges faced by such studies are: the inclusion of appropriate outcome measures to evaluate change on psychological interventions; insuring that the treatment modality which represents the background condition remains relatively constant during the course of the study; and insuring an adequate timeframe in which to evaluate effects of psychological treatments (in the design where psychological intervention is manipulated).

The second class of studies adds a medication condition (or conditions) to a multiple-group design such as those discussed in the previous section. These studies examine the comparative effects of medication and psychological treatments and face greater challenges. They have been called "horse races" and may thereby contribute to guild conflicts between psychologists and psychiatrists (Kendall & Lipman, 1991).

Appropriate inclusion criteria for medication and psychological treatments may differ and compromises may be necessary. Such studies will generally include double-blind conditions for medication and also benefit from inclusion of independent assessors. The studies require expertise in both clinical psychopharmacology and the relevant psychological interventions. Insuring this expertise for a study usually requires close collaboration and mutual respect by investigators drawn from psychology and psychiatry. Outcome criteria need to include measures of dimensions that are hypothesized to be sensitive to change in both modalities being studied and the reasons for inclusion of specific outcome measures should be explicit. A detailed review of these and other methodological considerations can be found in an article by Kendall and Lipman (1991) and in the article detailing the research plan for the National Institute of Mental Health Treatment of Depression Collaborative Research Program (Elkin, Parloff, Hadley, & Autry, 1985).

Finally, factorial designs provide explicit tests of both additive and interactive effects of medication and psychological treatment. These designs will be considered in Section 3.03.5.4.

An example of a study that compared medication and a specific psychotherapy is the study of prevention of recurrence of depression by Frank et al. (1990). Patients characterized by recurrent depression (at least two prior episodes) were treated with medication and manual-based interpersonal psychotherapy (IPT) (Klerman, Weissman, Rounsaville, & Chevron, 1984) until symptom remission was documented and maintained for 20 weeks. One hundred and twenty-eight subjects were then randomized to one of five treatment conditions: a maintenance form of interpersonal psychotherapy (IPT-M) that was characterized by less frequent visits; IPT-M and an antidepressant (imipramine) at the acute treatment dose; IPT-M and medication placebo; medication clinic visits and imipramine; medication clinic visits; and medication placebo. Subjects were treated for three years. Therapists were trained and certified by the developers of IPT. The major difference from the published manual is described as visit frequency. The major outcome examined was recurrence of depressive episodes during the three-year period. The two treatment arms that included imipramine (IPT-M and imipramine; imipramine and clinic visits) had the lowest risk of recurrence. Mean survival time was more than 83 weeks. The two groups that received IPT-M without medication (IPT-M alone; IPT-M and placebo) had a higher risk of recurrence; mean survival time was more than 60 weeks. The lowest survival time was seen in the group that received placebo and medication clinic visits; survival time was 38 weeks on average. The authors conclude that medication, at a relatively high maintenance dose, affords the greatest protection from recurrence in individuals who have experienced recurrent depression. However, psychotherapy, absent medication, represents a distinct advantage over clinic attendance coupled with a placebo.

The study has a number of strengths. Patients were randomized to treatment condition. There was an extremely low dropout rate (17%) over the three-year study duration. The design included control conditions for medication (placebo) and psychotherapy was administered under three conditions: alone, in combination with imipramine, and in combination with imipramine placebo. The psychotherapy followed an established manual and therapists were trained by the originators of the therapy. Survival analysis represents the most powerful statistical method for evaluating risk of recurrence.

Weaknesses include the limited examination of clinical outcomes. Although the authors mention the importance of judging interepisode social functioning, the article only examined recurrence risk. Second, the study population was, by design, limited to those who both had recurrent episodes and recovered from them. Of the 230 patients who met the first criterion, fully 42% did not enter the randomized trial. This represents a substantial limitation to generalization of the findings to depression broadly defined.

3.03.5.4 Factorial Designs

Designs that include at least two factors allow for detection of main effects in each factor as well as interactive effects. In the simplest of these, 2 × 2 designs, there is a control condition or at least two defined levels of each factor, as shown in Figure 1. If the factors represent independently defined treatment modalities, then such designs can detect the ability of one treatment to potentiate the other or even to inhibit the effect of the other. For this reason, such designs are particularly suited to examining the relationship of medication and psychological interventions. Uhlenhuth, Lipman, and Covi (1969), Schooler (1978), and Hollon and DeRubeis (1981) have considered factorial models for the study of the interaction of medication and psychological treatments. According to Uhlenhuth et al. (1969), there are four possible forms that the interaction can take. These are shown in Figure 1. An additive effect is defined as the simple sum of the effects of the two treatment modalities. The effect in cell 1 is equal to the combined effects seen in cells 2 and 3. The treatments may potentiate each other. In that case, the combined effect (cell 1) is greater than the additive sum of the two treatment effects (cells 2 and 3). The treatment modalities may inhibit one another. In that case the combined effect (cell 1) is less than the effects of each treatment independently (cells 2 and 3). Finally, there may be an effect that they call reciprocal, in which the combined effect (cell 1) is equal to the main effect of the more effective treatment (the effect seen in either cell 2 or cell 3). Detection of all these effects depends on the factorial design and the presence of cell 4 which represents the combined control condition or as it has sometimes been dubbed, the double placebo.

Factorial designs are potentially a valuable model for examination of other important variables in understanding treatment, for example, to control for the effect of setting in studies that are conducted in more than one clinical setting. However, the most important use, from the perspective of this chapter, is to study the relationship of medication and psychological treatment.

Marks and his colleagues (1993) studied the effects of medication and a psychological treatment for panic disorder. There was prior evidence of efficacy for both the medication, alprazolam, an antianxiety drug, and the experimental psychological treatment, live exposure. One hundred and fifty-four subjects were randomly assigned to four treatment conditions: alprazolam and exposure (AE cell 1, Figure 1); alprazolam and relaxation, the control for the psychological treatment (AR cell 2, Figure 1); placebo and live exposure (PE cell 3, Figure 1); and placebo and relaxation, so-called double-placebo (PR cell 4, Figure 1). Pharmacologic and psychological treatment lasted for eight weeks, medication was tapered during the following eight weeks and subjects were followed for an additional six months to assess relapse or maintenance of gains following discontinuation of treatment. Both exposure and relaxation followed published guides, not treatment manuals (Marks, 1978; Wolpe & Lazarus, 1966). The study was conducted at two centers; one in London, UK, and the other in Toronto, Canada.

The primary outcome measures were: ratings of avoidance by an assessor and the subject; the number of major panics; work and social disability; and the clinician's rating of improvement. After eight weeks of treatment, there were significant main effects of both alprazolam and exposure. The effects of alprazolam, as would be expected for a pharmacologic treatment, did not persist during follow-up, whereas the effects of exposure persisted after treatment discontinuation. Interpretation of findings is complicated by the fact that there was substantial improvement in total major panic in the "double-placebo" group that received medication placebo and relaxation.

In addition to reporting statistical significance of outcome measures, the article also reports the effect size of various outcome measures (Cohen, 1988, 1992). With large samples, differences that are clinically uninteresting may be statistically significant, that is, they are unlikely to be due to chance. The effect size is less influenced by sample size and may therefore be considered a better indicator of clinical relevance. During the first eight weeks, when both treatments were being delivered and were significantly better than their controls, the effect size is larger for exposure than for alprazolam. According to the definitions of Uhlenhuth et al. (1969), this would be a

		Psychological treatment	
		Experimental	Control
Pharmacologic treatment	Experimental	1 Alprazolam/exposure	2 Alprazolam/relaxation
	Control	3 Placebo/exposure	4 Placebo/relaxation

reciprocal effect. Effect sizes are moderate to large for alprazolam and very large for exposure according to criteria defined by Cohen (1992). The effect sizes diminish over time for exposure but are still in the large to very large range after six months. Those for alprazolam are absent to small during the follow-up period. Effect size for total major panics are absent to small throughout the study because of the effect in the control group. In general, the findings show a greater effect for exposure and no consistent pattern of interaction between psychological treatment and medication.

The strengths of the study include an appropriate population for study. All subjects met stringent criteria for panic disorder and none had been nonresponders to either of the treatment modalities prior to study entry. Further, assignment to treatment was random, assessment was double-blind to medication and single-blind to psychological treatment, assessment included both self- and assessor-completed measures, and analyses addressed the range of assessments included.

The design reveals one of the problems inherent in studies designed to assess interactions of medication and psychological treatments. The discontinuation design, that was appropriate for the psychological treatment in the present study, is not optimal for assessment of pharmacologic treatments and the fact that pharmacologic effects were not maintained after discontinuation should come as no surprise. Analysis was restricted to 134 subjects who completed at least six weeks of treatment (a 16% dropout rate). Although the rate is relatively low compared to other studies of alprazolam, and there were no differences in baseline characteristics between the 20 subjects who withdrew from the study and the 134 who did not, it is unclear how their inclusion in analyses might have altered the results. The general wisdom regarding randomized clinical trials is unequivocal in stating that all subjects randomized must be included in analysis but a review of a standard journal in the field, *Controlled Clinical Trials*, during the past four years did not reveal a single specific citation.

3.03.6 INDIVIDUAL DIFFERENCES: WHAT TREATMENT WORKS FOR WHOM?

From a clinical perspective, perhaps the most important question regarding treatment is the appropriate matching of patient or client to treatment. The idea that a given treatment approach is appropriate for all (even all who share certain characteristics) runs counter to clinical and research experience. Although randomized experiments may not represent the optimal method for evaluating this question, they can provide useful information. Two rather different methods can be used in the context of randomized trials. The first is the use of factorial designs and the other is the *post hoc* examination of individual characteristics as predictors of treatment response. This section will consider these methods.

3.03.6.1 Individual Difference Variable

The use of an individual difference variable as a factor in a factorial design allows a direct experimental test of a hypothesis regarding differential effects of a patient or client characteristic in relation to a psychological treatment. This strategy is difficult to implement—each client characteristic included doubles the number of subjects needed in a study. Perhaps the most common example of a client characteristic studied in this way is the use of more than one center in a study so that the generalization across centers can be tested. Examples of this strategy are relatively common (e.g., Elkin et al., 1989; Marks et al., 1993), but it is unusual for hypothesized differential effects to be proposed. A second variable that is sometimes investigated in a factorial design is gender.

3.03.6.2 *Post hoc* Examination of Predictors of Treatment Response

In general, *post hoc* analyses of individual client characteristics as differential predictors of treatment response have been disappointing. For example, several of the studies that are reviewed in this chapter have attempted to identify characteristics of clients who fare particularly well in the treatments studied and as has been noted in the descriptions, reliable differences have not been found. Review of the psychopharmacology literature yields a similar conclusion.

Perhaps the most reliable finding regarding prediction of treatment outcome has been severity of symptoms. In a number of studies where symptom severity has been studied, the evidence suggests that it usefully discriminated response (e.g., Elkin et al., 1989). In that study, discrimination of differences between medications and psychotherapies was clearer among subjects with greater symptom severity.

Difficulty in reliable identification of individual characteristics that predict differential response may stem from a number of causes. The nihilistic view is that there simply are no reliable predictors. Two alternatives seem more reasonable. The first is that although studies may have adequate power to detect treatment differences, they do not have adequate power to examine individual characteristics. If this is the case, meta-analytic strategies could allow the examination of data regarding characteristics that are frequently considered such as gender, age, symptom severity, duration of symptoms, referral source, comorbid psychological problems, or diagnoses. See Chapter 15, this volume, for a discussion of this problem and methods to deal with it. The final alternative is that client characteristics which are predictive of treatment outcome are elusive and are not captured adequately in experimental studies. Characteristics such as motivation and client–therapist rapport come immediately to mind.

3.03.7 CONCLUSIONS

Randomized, experimental designs represent a useful method in the evaluation of psychological treatments. They allow unambiguous conclusions regarding the treatments that are studied in the subjects who receive them. This chapter has reviewed in some detail several generally excellent individual studies in order to identify their strengths and weaknesses. The astute reader will have noted that all the studies had both strengths and weaknesses. The goal of drawing attention to these is twofold. The first is to provide readers of the research literature with a framework within which to evaluate other studies. The second is to hope that the observations in this chapter may contribute to the ongoing process of improving the quality of experimental studies of psychological treatments. In this way we can maximize the value of the contributions made by subjects who agree to participate in experiments and improve the treatment and care of clients and patients.

3.04.1 INTRODUCTION

3.04.1.1 The Relevance of Experimentation in Clinical Psychology

Contributions of clinical psychology to health services have received widespread recognition and the benefits are undisputed. The parallel increase of costs in such services due to growing utilization of psychological aids, however, must be justified on grounds of the scientific method. There is a double need for valid and reliable demonstration of the value in technology derived from and offered by clinical psychology: efficacy in serving the customer and efficiency legitimizing it to the supplier must be shown. Quasi-experimental multiple group comparison designs are well-suited for this task: they account for the fact that randomization may often not be an adequate sampling strategy in real-life clinical research situations and still allow for assessment of absolute and relative efficacy of psychological interventions. They help evaluate the merits of different components in interventions and support decision making as regards implementation, monitoring, and optimization of respective programs. This practical, if not wholly pragmatic, research and reasoning contributes directly to either correction or refinement of the present state of scientific knowledge and development in the domain of clinical psychology. It is practice where results from clinical psychology are to be evaluated, and it will be seen that multiple group comparisons offer adequate tools to do so.

3.04.1.2 Terms: "True," "Quasi-," and "Non-" Experimental Studies

In this chapter, multiple group comparisons will be focused on by means of quasi-experimental designs. Delimiting characteristics to distinguish the three kinds of empirical research situations quoted above are subject assignment, modus of treatment, and control. It is agreed widely to speak of true experiments when both random subject assignment and creation of treatment or, in a broader sense, active manipulation of conditions occur. In a quasi-experimental setup the first condition is weakened, and in observational studies both conditions are completely released. Some authors refer to the term quasi-experimental as to the constraint that the researcher cannot deliberately assign subjects to conditions or that occurrence of a treatment is only a typical but not necessary feature (e.g., Spector, 1981). In this case, the differentiation to pure observational studies seems obsolete. It is argued that any experimental situation, be it "true" or "quasi," involves an arbitrary discernible kind of treatment, by creation or manipulation of conditions regardless of mode of subject assignment, and that quasi-experiments feature all elements of true experiments except randomization.

If there is no manipulation of subjects or conditions in order to evoke variation in dependent measures (and thus contrasts for testing), reference is made to "pure" observational studies (see Chapters 4 and 13, this volume). The main problem then lies with selecting a statistical model and further in devising an appropriate parametrization that reflects as closely as possible the structure of scientific hypotheses (in their original, verbal form). The objective of such inquiries may comprehend the identification of latent traits and their structural composition (factor analysis), the identification of the dimensional metrics according to which subjects determine the relative value of different objects (multidimensional scaling/conjoint measurement), or in the identification of a time series regression model in order to predict value and stability of a criterion. In neither case is a treatment strictly required.

3.04.1.3 The Concept of an "Effect"

Multiple groups comparison experiments are conducted in order to demonstrate relative effects of treatment. Effect hypotheses refer to presence, size, and variability of effects with respect to certain criterion measurements. The major objective of multiple group comparison designs lies with the generation of data in order to test such hypotheses. Subjects or groups methods representing different levels of independent variables or being subjected to different kinds of treatment, eventually measured at different points of time, are compared on data obtained in the same way in each group and at each occurrence. Then a classical concept of an "effect" is identified with the interaction of the subject or group factor and time/treatment with respect to the outcome measure. For example, the idea of a case–control study to determine therapy effectiveness might be pointed out as "if you apply X (treatment, independent variable) in one group, while not in another, and you observe a significant difference in Y (some functional status, dependent varable) between both groups, then you have reason to believe that there is a relationship between X and Y, given all else being equal." It will be seen that it is the *ceteris paribus* condition in the given clause, and how it is tentatively realized, that makes (quasi-)experimentation a delicate challenge to researchers' creativity and expertise.

A worked example of a quasi-experiment is chosen to introduce into the present chapter an illustration of some of these challenges and ways to counter them.

Worked example: Outline

In a very well designed study, Yung and Kepner (1996) compared absolute and relative efficacy of both muscular and cognitive relaxation procedures on blood pressure in borderline hypertensives employing a multiple-treatment–multiple-control extension of design Number 6 in Figure 2. It is reported that most clinical applications make use of an amalgam of cognitive techniques like suggestion, sensational focusing, and strict behavioral training of muscle stretching relaxation. The authors aim at partialing out the effects of these various components by clearly separating instructions that target muscles directly and such instructions that try to mediate muscle tension by mental efforts. As a consequence, special attention is given to operational validity and treatment integrity. In order to counter confounding of subject characteristics and procedure variables the authors devise a rigorous subject selection and assignment policy which makes their work an excellent example for the case here.

Before engaging in describing various designs and methods of data analysis, and in evaluating this particular experiment, it seems instructive to outline a general process of experimental research.

Generally, it will not be possible to observe all possible instances of variable relations (which would innecessitate inference), but evidence for the hypotheses will be sought by investigating subsets of the population(s) in which these relations are considered to hold true. Sampling variability and measurement error lead to the use of statistical models in order to determine the genuity of an observed effect. Effect sizes (ES) serves to model the above "difference" in terms of statistical distributions (which, in turn, provide both the mathematical background and the factual means for testing effect size). The significance of statistical significance and the concept of reason based hereupon are evaluated in Chapter 14, this volume, and the issue of interpreting such a relationship as causal is briefly discussed in Section 3.04.3. But how does one arrive at effect hypotheses and corresponding statistical models in the first place?

3.04.2 THE LOGIC OF DESIGN IN THE COURSE OF EMPIRICAL RESEARCH

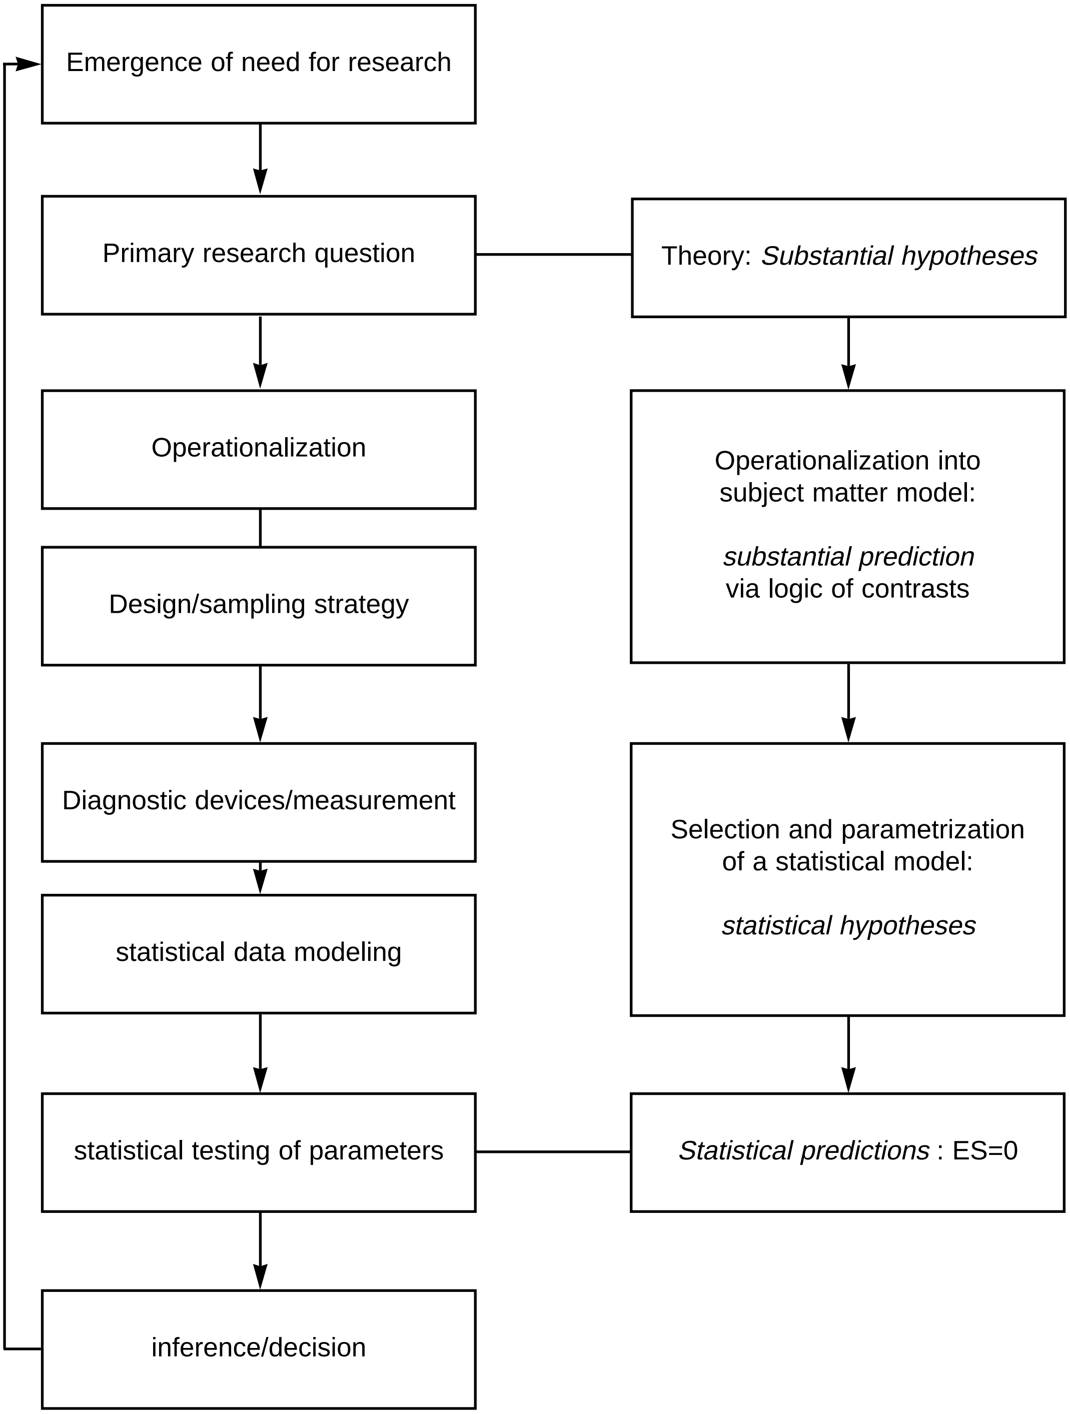
It is suggested that experimentation as a procedure is a special realization of a general process of empirical research, as depicted in Figure 1. Whether experimentation is seen as an appropriate access to address the problems in question depends on preceding decisions; if so, choice of design and sampling structure is conceived as an embedded level. Furthermore, it is proposed that this procedural outline is paralleled by a conceptual process of hypotheses derivation. Figure 1 illustrates this correspondence with hypotheses levels according to the deductive four-step model presented by Hager (1992):

(i) Generally agreeing with the hypothetico-deductive method, scientific hypotheses are derived from proposition structures in theory. Sometimes, mere need for evaluation or striking observations from practice must serve as a starting point for the research process.

(ii) Relative to marginal conditions (resources, time, etc.) and constraints in construct operationalization, a subject matter model is derived in terms of variables and their interrelation. Temporal ordering and other prerequisites of model theory guaranteed, predictions regarding empirical manifestations are derivable ("should then be higher than"). Devise a design now in order to translate a hypothesized structure of variables into a measurable one and a sampling strategy in order to actually perform the measurement. Hypotheses stating that certain strategies of verbal intervention in psychotherapy are of use for depressives might be translated into a "better-off" proposition as quoted in the text above. It is clear that, at this level, an experiment rationale is suggested: comparison of groups. Also, global aspects of testing are implied: assessment strategy (will psychometric tests be applied or will therapists rate patients' depressiveness by virtue of their expertise?), or inference conditions (will an effect be required to instantiate simultaneously on all criteria and to be stable for at least a year, thus calling for multiple post-tests, or will the whole study be replicated using different subjects and other therapists?). In transition to the next level, a set of decisions to be made is encountered that are known to statistical consultants as "how many" questions in project and design planning (how many subjects are enough per group in order to balance sensibly factors of sensitivity?, how many time intervals make up the optimal retest interval?, how many outliers can be tolerated in and across groups?, etc.).

(iii) Multiple group comparison as a conceptual strategy implies suppositions about structures in the data. Here, conceptually identified effect sizes receive an accurate, quantitative, and thereby testable formulation. A "pre–postdifference" between groups may now be specified in terms of an expectation of a difference in central tendency of an outcome variable, a kind of second-order comprehensive measure that can be tested easily for significance at the next level. More generally, statistical predictions formally denote compound suppositions about the "behavior" of data, and a "good" design generates data behavior that by maximum degree either confirms or contradicts behavior that would be expected by hypothesis.

(iv) Statistical hypotheses are statements about specific values, variability, and ordinal or metric relations of parameters of distributions which follow from statistical predictions. A common prototype for such a measure is



Emergence of need for research
Primary research question
Theory: *Substantial hypotheses*
Operationalization
Operationalization into subject matter model:
substantial prediction via logic of contrasts
Design/sampling strategy
Diagnostic devices/measurement
Selection and parametrization of a statistical model:
statistical hypotheses
statistical data modeling
statistical testing of parameters
Statistical predictions : ES=0
inference/decision

Figure 1 The process of empirical research.

given by $ES = (\mu_{\text{treat}} - \mu_{\text{control}})/\sigma_{\text{control}}$. Its problems not withstanding, this is considered a fairly reasonable and intuitive basic concept. Various other ES formulations can be translated to it (Cohen, 1988; Lipsey, 1990). For instance, in the example of therapy effectiveness, and effect is assumed to be present when statistical testing has determined that its ES differs from zero significantly, that is, beyond the expected limits of sampling error and with prespecified error probabilities of the α- and β-kind. In fact the probability is always estimated that there is no effect (therefore speaking of "null" hypotheses) or that, as it is frequently put in terms of sampling theory, comparison groups are samples that were drawn from the same population. In this case, observed differences merely reflect sampling error. Depending on the formulation of predictions, it is not always obvious at first sight whether these "null" probabilities are required to be high or low. Further complicating things, a statistical prediction must sometimes be further differentiated into a set of single-testable statistical hypotheses. It must then be decided whether an overall null (or alternative) hypothesis is conforming to the compound statistical prediction or what pattern of acceptance or rejection of individual hypotheses integrates to a favorable finding. Moreover, there is a need to decide whether integration of separate findings should follow a disjunctive (compensatory) or conjunctive rule (e.g., must depressives benefit on all scales applied in order to justifiably speak of an effect). As a consequence of this multiple testing, there is a need to control for accumulation of error probabilities. Note, however, that "difference" does not necessarily imply the comparison of means. It most cases, pretest-standardized differences in means are in fact used for this purpose because such measures have known statistical properties (e.g., distributions and standard errors) following normal theory and can thus be easily tested statistically. But a test might be made for a ratio to be greater than a prespecified number (as is done frequently when using differential model fit across groups as a criterion) or the inequality of regression intercept and slope parameters (as featured in regression continuity designs, see Section 3.04.5.7). The general rationale is to determine whether or not groups differ in any statistical parameter and to relate this difference to a reference sampling error estimate. (For details on procedures of significance testing see Cohen, 1988; Fisher, 1959; Giere, 1972; Mayo 1985.) Criteria like adequacy (on each level, hypotheses preserve to maximum degree classificatory, ordinal, or metric relations assumed on preceding level), sufficiency (a linearly predictable trend may not be tested for monotony only), decisiveness and unambiguous identification of theory-conforming empirical states (Hager, 1992) serve to estimate validity of hypothesis derivation. After statistical testing, however, there is a need to work backwards: what effect size is considered practically significant? Is there a failure in predicting things as they should occur in theory? Do the findings entitle inductive inferences to be drawn to higher levels in the hierarchy of hypotheses, leading to tentative confirmation of propositions in the theoretical frame of reference? Here have been introduced some of the most serious problems in philosophy of science, and there is a need to get still further into it before turning to techniques.

3.04.3 CRITERIA: SENSITIVITY, VALIDITY, AND CAUSALITY

Conventionally, the major objective of experimentation is seen in demonstrating a causal relationship between phenomena, or, as Cook and Campbell (1979) put it in more correct terms, in facilitating causal inference. The logic underlying experimental design is an implicit variation of the concepts of covariation, temporal precedence, and of ruling out alternatives. This means, in terms of experimentation, that the hypothesized "cause" should be capable of being omitted and control group esigns are preferable. One-shot case studies or pretest–post-test designs without at least one control or, in a broader sense, a comparison group, do by no degree allow for the kind of inference scientists are most interested in: causal ones. But, as was seen from Figure 1, experimentation ends up in statistics. The result of an experiment is that data are communicated in the form of statistical propositions. Whether statistical relationships should be taken as indicators only or be conceived as "causal," "functional," or "probabilistic" cannot be determined by simply rating how well the rules of experimentation were obeyed, but depends on affiliations in philosophy of science. Criteria for when to apply the predicate causal and be justified in doing so, are hardly available. But before drawing any such inferences it will be necessary to (i) ensure sensitivity in order to detect the effect and (ii) rely on it being a valid indicator for what is to be interpreted as causal. In the following section, a start is made on practice by introducing the key concepts whose consideration will hopefully establish a sensitive, valid, and meaningful design. It is clear, however, that an evaluation of meaning must rely on protoscientific argumentation.

3.04.3.1 Sensitivity

Sensitivity refers to the likelihood to detect an effect in sample-based investigations, given it is indeed present in the population from which samples were drawn. It is determined by sample size, total and direction of effect size, heterogenity of both subjects and treatment applications, and various undesired features of diagnostic devices (unreliability, etc.). While those factors affect experimental precision, others like prescribed error probabilities of both α and β type and the kind of statistical test used affect the associated concept on the level of statistical analysis: power. It must be borne in mind that sampling error stands for the variance of parameter estimates and is, thus, maximally dependent on sample size. As a consequence, an effect size however small will become significant in statistical terms with increasing sample size, while being wholly uninformative for practical considerations. For an ES of the kind presented above less than or equal to 0.3 to attain statistical significance at $\alpha = 0.05$, some $n = 300$ subjects would be in order; for an ES of 0.5 still a hundred or more. In a meta-analysis on psychotherapy efficacy Grawe (1992) found that 87% of 897 studies were using samples of $n = 30$ or less subjects in intervention groups. To attain statistical significance at the usual level an effect size of greater than 1.20 would then be required. This may be considered quite an unlikely prerequisite: in their meta-analysis on psychotherapy research Smith, Glass, and Miller (1980) reported an overall expectation of treatment effectiveness of no more than ES = 0.85. Tentative counterbalancing the determinants of effect sizes other than the "true" effect (population effect), namely sample size, error probability, and assumed ES, is best achieved using power tables as proposed in Cohen (1988). Since detecting an effect usually means observing an effect size that statistically differs from zero, the levels of design and data analysis in Figure 1 become mixed up when evaluating the whole procedure of quasi-experimental multiple group comparisons. It is the correspondence of design structure "giving" the data and statistical data model that establishes a "good" design. Sometimes data obtained from one design can be translated into different models (problem of parametrization) and effect sizes may be evaluated for their significance by various of statistical tests (problem of relative power).

3.04.3.2 Validity

Validity refers to the likelihood that the effect detected is in fact the effect of interest. Campbell and Stanley (1963), and Cook and Campbell (1979), originators of the concept, distinguish internal, external, and statistical validity as well as construct validity. The latter refers to operationalization problems (mono-operationalization bias, monomethod bias, evaluation apprehension, experimenter expectancies, etc.). Internal validity evaluates to which extent variation in measured dependent variables is attributable solely to variation of independent variables or treatment, respectively. Again, assuming an effect for a difference in the value of some statistical parameter calculated from data on dependent variables (e.g., the mean), internal validity assures that nothing but treatment "caused" this difference, and that, as Lipsey (1990) puts it, the observed difference parallels the fact that "the only difference between the treatment and the control conditions is the intervention of interest" (p. 11). This, of course, relies heavily on the experimenter's ability to control for other possible "sources of variation" or undesired confounding influences. External validity refers to the extent to which results obtained from a sample-based study may be generalized to a specified population from which samples were drawn in the first place and/or across slightly different (sub)populations. Such extrapolation must be reasonably justified as regards target population (i.e., persons), settings, and future time. Note that representativeness is a prerequisite to external validity that not only holds for subject selection but also for situative conditions of experimentation itself: ecological validity must be given careful consideration especially in clinical fields.

Campbell and Stanley (1963) have raised the argument that internal validity can be thought of as a necessary while not sufficient condition for external validity. Note, however, that some methods of control depicted in the next section show conflicting effects on internal and external validity, and to compensate for these imbalances with a reasonable trade-off certainly is an art of its own. Most flaws in experimental and quasi-experimental design boil down to violations of factors of validity which is why a short outline is presented (see Table 1) of their respective factors as designated by Cook and Campbell (1979). A far more comprehensive listing of possible threats to validity and various other shortcomings in planning experimental research is presented in Hoole (1978). Special attention to external validity in evaluation contexts is given in Bernstein (1976).

Admittedly, full consideration of all these caveats, if not mere apprehension of this rather lengthy list, seems to discourage any use of (quasi-)experimental designs at all. The contrary is true, though. There will be a benefit from

Table 1 Factors of internal and external validity.

Internal validity	
History	In the time interval between pretest and post-test measure, various influences or sources of variation that are not of interest or that may even distort “true” findings may be in effect besides the applied treatment. This clearly leads to confounding. Also, these factors may be differently effective for different subjects, thereby introducing additional error variance. Controlling for such intrusion by elimination or by holding it constant to some degree is an appropriate method in laboratory settings but is almost impossible to achieve in real-world clinical (field) settings (apart from identifying such factors as relevant in the first place). Moreover, many disorders are known to be subject to seasonal variation or others periodicities.
Maturation	In longitudinal studies with fairly large restest intervals, effects may be confounded with or entirely due to “natural” change in subjects’ characteristics that are correlated with the variables and treatments of interest. A prominent example in clinical research is spontaneous remission in psychotherapy studies. The hope is that such change takes effect equivalently in both groups of a case–control study (which again is rather a “large sample” argument but is usually held true for randomized samples).
Mortality	In repeated measures designs, attrition or loss of a certain proportion of subjects is to be expected on a regular basis. Differential loss, however, means that the observed drop-out pattern across groups seems not to be random but is dependent on variables that might correlate with treatment or outcome measure. This in turn introduces *post hoc* selection artifacts and is likely to erroneously contribute to effect size in that it may change value and variability of post-test statistics.
Statistical regression	A typical problem with measuring change lies with regression towards the mean. Subjects may shown gain or loss in scores from pretest to posttest solely due to the unreliability of the test. This may be compensated for to a certain degree by multivariate assessment of dependent variables. Moreover, differential effects are likely to fall into place depending on subjects” pretest or starting-off: “viewed more generally, statistical regression (a) operates to increase obtained pretest–post-test scores among low pretest scores, since this group’s pretest scores are more likely to have been depressed by error, (b) operates to increase obtained change scores among persons with high pretest scores since their pretest scores are likely to have been inflated by error, and (c) does not affect change scores among scorers at the center of the pretest distribution since the group is likely to contain as many units whose pretest scores are inflated by error as units whose pretest scores are deflated by it.”[a]
Testing, instrument reactivity, and sensitization	In repeated measures designs subjects are likely to become familiar with diagnostic devices or may carry over pretest scoring behavior. In addition, there are many ways that testing procedure itself may affect what is tested. Items that evoke strong emotional reactions may distort scoring in subsequent ability subtests by increasing subjects’ unspecific arousal. Moreover, pretests may sensitize subjects for treatment reception by enhancing attention for certain attributes or by facilitating self-communication and introspection. Sometimes it is possible to control for this effect in quasi-experimental settings by applying strategies similar to the Solomon four-group design (see Chapter 3, this volume).
Selection/ interactions with selection	Selection is a threat to internal validity when an effect size—a difference in some parameter across groups—reflects pre-experimental differences between cases and controls rather than differential impact of treatment. Note that inference from such experimentation relies heavily on the *ceteris paribus* condition (denoted in the given clause in the outline in Section 3.04.1.3), and that systematic differences across groups due to selection bias are most pervasive in quasi-experimentation where we have to do without randomization. This is especially true in case of clinical treatment: one would not want to allot inhouse patients or program participants to different treatments (or exclude them to serve as controls) by random numbers but according to their individual needs and aptitude. Patients assigned for cases on behalf of equal (that is, equivocal) diagnoses may yet still differ from other patients in their group (error variance) as well as from controls in a whole pattern, of other variables that are likely to be related to both reception of treatment and outcome measures (e.g., hospitalization, socioeconomic status, verbal fluency, etc.). Note that most factors of internal validity listed so far may interact with subject selection, producing differential effects and thereby increasing experimental error.

Table 1 (continued)

Instrumentation	In the first place it must be ensured, of course, that diagnostic devices meet criteria of reliability, objectivity, and validity in terms of measurement and testing theory. In repeated measures designs, discrimination and differentiation capabilities of tests may change. Thus a gain in scores from one occasion to another may partly be due to enhanced performance of observers who improved skills with practice, and less due to differential effects of applied treatment at these occasions. A related problem lies with so-called floor or ceiling effects. Subjects scoring at the upper end of a scale on one occasion, say 6 on a 1–7 Likert scale, may easily report a decrease by half but will find it difficult to state a major increase of similar proportion. Note that clinical samples are often defined by a shift in mean in certain indicators with respect to a "normal" population.
Control group behavior	Besides the problem of recruiting and maintaining a control group, "compensatory rivalry" of respondents receiving less desirable treatment and "resentful demoralization" of such subjects are further threats to internal validity. In the first case, being assigned to the nonreceiving group may motivate subjects to behave competetively as to reduce the "true" effect (due to treatment) in counter-hypothesized direction. In the second case, the deprived get more deprived and less motivated: a patient that suffers from his disease is assigned for a control and thus kept from a therapy that is thought to be efficient by the experimenter. The "lose-heart" effect would then artificially enlarge effects. Both variants are of great practical importance in therapy effectiveness research.[a]
External validity	
Interaction of pretest and treatment, reactivity	It is well-known that mere knowledge to participate in a study or the awareness of being observed does affect behavior. Furthermore, due to sensitization effects or conditioning effects (see above), results obtained from samples that have completed a pretest cannot be fully generalized to populations that have not done so.
Interaction of selection and treatment	People that deliberately demand for psychological care or for access to health care programs are likely to be more susceptible to treatment or motivated than are accidental samples of convenience (collective of inpatients, rooms, etc.). Often, selection processes that have led to admission of subjects are unknown. It is clear, however, that results obtained from such samples cannot be generalized unreservedly.
Interfering treatments	Parallel, overlapping or interacting treatments lead to confounding and thus constitute a major threat to internal validity. But there are undesirable consequences for external validity as well. Suppose patients are receiving medical treatment in ascending dosage. Due to idiosyncratic effects of cumulation, conclusions drawn with respect to an intermediate level of dosage that generalize across people may be erroneous.
Nonrepresentative samples	Generally, target populations must be clearly specified in advance. In quasi-experimental design, representativeness cannot be ensured by random sampling on a large scale but instead take advantage of "natural" (nonmanipulative) sample formation. Often characteristics of research context naturally differentiate subjects into groups (rooming policies of hospital, record analysis, etc.). Strictly speaking, since there is no real sampling there is no point in making inferences. But this aside, sampling should not refer to subjects only: generalizing also includes care givers (therapists, etc.), hospitals, and regions. Therefore, another strategy lies with deliberate sampling for heterogeneity with respect for certain attributes relevant to the research question. Inference would then be across a wide range of units holding subsets of these attributes, but still limited to the respective superset. When dealing with clinical samples, this method seems fairly reasonable.

Source: Cook & Campbell (1979).[a]

it in that the degree to which attention is given to these issues prior to experimentation parallels the degree to which results can be interpreted and inferences drawn after experimentation. Factors of validity thus serve as criteria for comparative evaluation of quasi-experimental studies, they are not meant as a checklist for building the perfect one (remember that several factors exclude mutually). Another precaution must be added. While the bearings of internal validity on technical issues in research planning are widely agreed upon and factors listed above have nearly become codified into a guide on design construction, most important issues of construct validity often receive less recognition. But re-examining the procedural structure of empirical research, as sketched in Figure 1, the view that emerges is that everything begins and ends with valid operationalization of constructs into measurable variables, and of hypothesized relations into exercisable methods for "visualizing" them. Greater appreciation of construct and derivation validity is advocated before turning too readily to tactics and techniques of experimentation. For instance, one should examine treatment integrity well before constructing sophisticated application schedules in an interrupted time series design (see Section 3.04.5.3). Nonetheless, within the entire validity framework, causal inference is predicated on maximum appreciation mostly of internal validity. The question is what is meant by causal.

3.04.3.3 Causality, Practice, and Pragmatism

However sensitive and valid a design might be by these terms, an effect or statistical relationship cannot be interpreted as truly causal in an objectivist ontological sense or in the traditional Humean readings (for an introduction, see Cook & Campbell, 1979, and Salmon, 1966). Therefore, and for the following reasons, a wholly alternative view is pledged on these issues in the tradition of James and other pragmatist reviewers of methodology. Scientific inquiry and its results (e.g., explanations) should always bear technological relevance. As one consequence, the importance of manipulation, is re-emphasized as a feature of treatment in quasi-experimentation. Consider the following argument raised by Collingwood (1940):

> Suppose one claimed to have discovered cause of cancer, but added that his discovery would be of no practical use because the cause he had discovered was not a thing that could be produced or prevented at will. His dicovery would be denounced a shame. (p. 300)

Collingwood's point is that causal explanations are often valued for the leads they give about factors that can be manipulated. If the essential cause of some effect does not imply controlling the effect (e.g., cancer) through manipulating some factor, then knowledge of this cause is not considered useful by many persons (Cook & Campbell, 1979). Scientific inquiry and quasi-experimental research designs are conceived as concretization devices, as tools to obtain technological knowledge. Thus, research designs need to take into account the feasibility of manipulation of conditions that produce effects in order to at least allow for transfer into practice. It is practice where results from research in clinical psychology should be evaluated, which is why a concept of causality and explanation is needed that is of relevance. Modern philosophers and methodologists have demonstrated successfully that pragmatist reasoning can be adapted successfully to methodology in social sciences, and have done so down to the level of hypotheses testing (Putnam, 1974). Of course there is no pragmatic explanation of its own right. But our attempts to explain phenomena on experimental or even statistical grounds can be justified pragmatically by introducing criteria beyond a "logic of discovery":

> The first and ineliminable criterion for the adequacy of an explanation must be based on what it does for a man who wants explanation. This depends on contextual factors that are not reflected in the forms of propositions or the structure of inferences. (Collins, 1966, p. 140)

> Knowledge of causal manipulanda, even the tentative, partial and probabilistic knowledge of which we are capable, can help improve social life. What policy makers and individual citizens seem to want from science are recipes that can be followed and that usually lead to the desired positive effects, even if understanding the micromediational is only partial and the positive effects are not *invariably* brought about. (Cook & Campbell, 1979, p. 28)

If efficacy of, say, a new drug has been demonstrated on a statistical basis by experimentation, it is not possible, strictly speaking, to conclude that deficiency in effective substance of the drug caused the disease or that the substance now reversed the pathogenetic process to regeneration. Having controlled for side effects, it is perfectly justifiable to maintain the drug as a successful therapy (and raise funds for further elaboration which might give new insights for science as well as for refinement of the drug). On a statistical level this "better-off" thinking in interpreting results from case–control studies translates into the concept of statistical relevance (Salmon, 1966) or into the notion of Granger causality. The latter derives from the theory of linear systems and defines causal relevance of independent variables ("causes") in terms of increased predictability of value and variability of dependent variables ("effects"). Prognosis should then be more precise with a relevant variable included in the model than with the variable removed, and good prognosis is definitely a very useful outcome of research (Granger, 1969). Good prognosis is, after all, a feature of operational models. This is what should be expected from experimentation in clinical psychology: identification of factors that influence etiology and the spread of disorders and derivation of operational models that in turn might aid to confront them.

3.04.4 CONTROL IN QUASI-EXPERIMENTAL DESIGN

Control aims at enhancing and balancing factors of internal and external validity following the max-con-min-rule formulated by Kerlinger (1973):

(i) *maxi*mize impact of independent variables on dependent ones,

(ii) while holding *con*stant factors of systematic intrusion, and

(iii) *mini*mizing the influence of unsystematic variables or error.

What is meant by factors, influences, and error? Control is always exerted over independent variables that contribute to effects. It is instructive to refine the term variable into four types relevant in experimentation. Systematic variance denotes differences between groups and, with reference to the definition of an effect size in Section 3.04.1.3, thus indicates the presence of "true" effects. In concept, it is solely attributed to explanatory variables, indicating treatment. Extraneous variables, however, are not a primary focus of a study but in cases of substantial correlation with dependent ones introduce error variance and do bias estimates of effects. Such variables may either be subjected to control or be left uncontrolled in one of two ways, depending on both sample size and subject assignment policy. In the latter case, randomized variables are let run freely in the hope that their effects will cancel out in the long run and thus equate groups in a probabilistic sense while confounded variables constitute a threat to validity that cannot be ruled out. It follows that controlled variables are extraneous but their impact on measures of effect is accounted for because error variance is reduced. If such erroneous influences are known to operate (by background knowledge introduced into the subject matter model, or simply by intuition), the techniques presented in Table 2 are used or at least an attempt is made to obtain accurate measures on them. Statistical techniques may, then, be used in order to separate *post hoc* the effect of treatment (in terms of ES) and selection differences.

In quasi-experimentation, control is exercised rather by means of subject selection or statistical analysis than by manipulating conditions. Because no randomization is used in quasi-experimental settings to wash out all initial differences in and across groups and because an effect has been defined in terms of post-test differences, credibility of findings will depend on the ability to demonstrate that groups have been alike as possible except for the difference in treatment they received. It will be noticed, however, that pretest equivalence does not lead, as might be implied by name, to equivalent groups. There may still be reliable and substantial differences on other factors relevant but left unconsidered (or even unmeasureable if known) that affect the phenomenon in question. The argument by Cook and Campbell (1979) is followed that only understanding the process of subject selection allows full understanding of subject differences that cannot be attributed to treatment, and that randomization must be considered the only model of such a process that can be completely understood.

The following is a worked example:—Control is by subject selection and assignment:

> Of 307 recruited individuals, only 40 were eligible for participation. Persons showing habituation effects were excluded, because their high pressure in multiple baseline readings was assumed to be a reaction to the measurement situation itself (sensitization). To control for treatment interference persons currently engaged in other pressure control techniques were also excluded. Persons on medication were asked to present medical records to assure constant dosage for the time of their participation (history). The authors cite evidence for a linear relationship between blood pressure level prior to behavioral intervention and treatment change. They further attribute contradictory results in recent research on relaxation efficacy to the common practice of matching experimental groups with respect to the average on certain blood pressure parameters, which leaves differential treatment susceptibility in higher degrees of hypertension uncontrolled. Subjects were therefore orthogonally matched on systolic blood pressure, age, and sex to assure pretest equivalence.

Experimental error also leads to bias in effect size estimates. While disturbing marginal influences (disruptions due to periodicities in hospitals" daily routines, noise, etc.) may be held approximately constant or be eliminated thereby having their influence equated in and across groups, other undeliberate variations of experimental conditions (e.g., treatment inflation or interferences) and measurement effects are to a far lesser extent under the control of the experimenter. But in many field settings there may be no desire to exert artificial control over such (in theory) irregular components of overall effect. It may be preferrable to preserve or enhance external or ecological validity when finally turning to generalization. Since practice is defined as primary, however, bias due to naturally varying concomittants is something to be faced. There is no need to put research back into the laboratory by excellent control when findings need to be transferred into applications for a noncompliant world.

The worked example is continued to demonstrate trial structure and procedural control:

Table 2 Controlling subject-induced extraneous variables.

Matching	The rationale of matching is to fully equate groups with respect to pretest scores, so that differential post-test scoring could legitimately be interpreted as differential change. The more variables are called in for matching the greater a shrinkage in sample size must be expected, sometimes deflating degrees of freedom to an extent where statistical analysis is no longer possible. Moreover, such samples may no longer be representative for target populations to which one finally intends to generalize findings. By the way, there is great appeal in the idea to match subjects with themselves across treatment levels as is the case, for example, in crossover designs.
Parallel groups or aggregate matching	This means of control is, in a way, a weaker version of matching by taking resort to group statistics rather than to individual values. The influence of confounds or, more generally speaking, nuisance factors is considered not relevant if it is distributed evenly across groups. If such a variable has equal distribution in each group (with respect to first- and second-order moments, e.g., mean and variance), groups are said to be parallel on this variable. When dealing with intact groups or when assignment is guided by need or merit, this strategy would entail exclusion of subjects in one group in order to approximate the other or vice versa. Again, sample size would be reduced and groups may finally differ on other variables by selective exclusion. Control always seems to trade off with external validity, notably generalizability. Parallel groups, however, are much easier to obtain than samples matched by score.
Blocking	Blocking further draws variance out of the error term when nuissance factor(s) are known and measurable on a categorical level. The rationale is to match subjects with equal score on this measure into as many groups as there are levels of the nuisance factor. If, for example, $n_j = 10$ subjects are to be assigned to each of $J = 3$ treatment conditions (factor A), and another factor B is known to contribute to variance, one would obtain $K = 10$ levels of factor B with $n_k = 3$ subjects each and then randomly assign $n_{jk} = 1$ subjects per B-level to each of the J levels in A. An increase in numbers of blocks will further decrease error variance since scores within a block of subjects matched this way are less likely to vary due to selection differences to the same extent than would have to be expected in blocks comprising more or all (no blocking) subjects. Note that in this model blocks represent a randomly sampled factor in terms of mixed-model ANOVA[a] and thus can enter statistical analysis to have their effect as well as possible interactions with treatment tested for. As a result, blocking could be viewed as transition of matching (above) into factorization (below). On the other hand, matching is but an extreme case of blocking where any pair of matched subjects can be considered a separate block.
Factorization	Confounding can be completely removed from analysis when confounding variables are leveled (measured by assignment to categories or by recording their continuous scale into discrete divisions) and introduced into design as a systematic source of variation. This generally results in factorial designs where effects of factors can be quantified and tested (main effect and interaction in fully crossed designs, main effect only in hierarchical or incomplete structures).[a,b,c]
Analysis of covariance	While factorization is a pre-experimental device of control (it gives, after all, a sampling structure), analysis of covariance serves to *post hoc* correct results for concommittant variables or pretest differences.[d]
Holding constant elimination	If hospitalization must be expected to substantially mediate results, a most intuitive remedy lies with selecting subjects with the same inhouse time. Strictly speaking, there is no way of generalizing to other levels of the hospitalization variable.

Source: Hays (1990).[a] Pedhazur & Pedhazur (1991).[b] Spector (1981).[c] Cook & Campbell (1979).[d]

All subjects received treatment, placebo, or pure assessment in equal time spacing in eight experimental sessions. They were instructed to replicate these sessions for 30 days after the laboratory trial and to keep a record of their practice. After this follow-up period, all subjects were finally assessed on their blood pressure. Though this procedure implicated a loss in standardization, it certainly enhanced ecological validity and increased the clinical relevance of the study's findings. Light and temperature were held constant in all measurement situations, all equipment was visually shielded to prevent feedback effects. Measurement equipment was calibrated before each trial. All participants spent equal time in the measurement setting and were blinded with respect to assessment results until completion of the measurement occasion. To control for experimenter effects subjects received live relaxation instructions in three sessions followed by five sessions with taped instructions. This procedure further improved standardization of treatment situations. A training time of 18–20 minutes was justified as optimal by recurring to recent findings that shorter training lacks any effects and that longer training often results in loss of motivation to practice, increased dropout rates, and reduced stability of effects over time.

3.04.5 A PRIMER SYSTEM OF DESIGN

As will be obvious from Figure 2, basic forms of designs mostly differ in whether or not they use randomization to assure initial group equivalence and control groups to determine effects, and whether or not they dispose of pretest, multiple observations, multiple forms of treatment (applied, removed, reversed, faded, etc.) and different controls. Following on from this, the regression discontinuity approach is presented as leading to a class of designs in its own right. In the case of more than one explanatory independent variable, additional decisions must be made regarding logical and temporal order of treatment application (factorization into fully crossed and balanced plans, incomplete and hierachical plans, balancing sequence effects, etc.). These topics are more fully covered in Chapter 4, this volume. Note that many important practical considerations and implications for choice of a statistical model for subsequent analysis are hidden completely in what is called the "data aquisition box" (or "O" in standard notation, see below). Here it must be decided on (i) number of dependent variables (uni- vs. multivariate analysis), (ii) various parameters of repeated measurement (number of occasions, lengths of retest intervals, etc.), (iii) order of dependent measures and error modeling (e.g., use of latent variable models), and (iv) scale characteristics of dependents (parametric vs. arbitrary distribution models).

Most authors, follow standard ROX terminology and notion introduced by Campbell and Stanley (1963): R stands for randomization, O stands for an observation or measurement occassion, X stands for treatment or intervention. Temporal sequence is expressed by left-to-right notation in a row, separate rows refer to different groups.

3.04.5.1 Selections from the General Scheme: Nonequivalent Group Designs

The designs shown in Figure 2, while not a focus of this chapter, will now be considered. Designs one and four are considered "pre-experimental" by Campbell and Stanley (1963):

	Single Group Study	Multiple Group Comparisons	
		"True" experiments	Quasi-experiments
Post-test Only	1 X O	2 R X O -------------------- R O	3 X O -------------------- O
Pretest and Post-test	4 O X O	5 R O X O -------------------- R O O	6 O X O -------------------- O O
Time Series Data	7 OO.....X.....OO	8 ROO...X...OO -------------------- ROO..........OO	9 OO...XO...OO -------------------- OO..........OO

Figure 2 A basic system of designs.

findings from such studies are most ambiguous since almost any threat to internal validity listed above may be an effect and left uncontrolled. As a consequence, and because experimentation is meant to demonstrate effects by assessing comparative change due to treatment while ruling out alternative explanations, these designs are commonly held inconclusive of effects. They are not recommended for the purposes sketched in Sections 3.04.1 and 3.04.3. Design three does implement an independent control group, but still remains inconclusive as regards the genuity of effects due to selection differences. In design four, subjects serve as their own control. With two measures only, little can be inferred about true effects since maturation and other time-relevant threats to validity remain uncontrolled. Extending the principle to design seven, however, leads to a typical time series design for basic impact analysis that to some extent allows for more control. Suppose a trend line is fitted to both consecutive pretests and post-tests: a discernible shift in intercept and/or slope parallel to treatment application would indicate presence of an experimental effect (a conceptually different, but technically similar concept will be discussed with the regression discontinuity approach). Without determination of such a "natural" trend a higher post-test level might reflect what should be expected from extrapolation of regularities in pretest values only, disregarding treatment. In other words, dependent variables might show a change in value that is due to natural change over time (inflation, deflation, or periodicities of the phenomenon under study). Using multiple observations does not rule out this possibility as would using multiple observations and control groups, but still make it highly unlikely for such a trend to go undiscovered. Some authors argue that lack of a control group may be of less importance for this reason. Delay in effect instantiation or special forms of temporal calibration of effects can be modeled by univariate intervention (or interrupted time series) analyses (see McDowall, McCleary, Meidinger, & Hay, 1980). Note, however, that group designs are still being dealt with exclusively where $N > 1$. Single-subject designs, even when presented in the same notation, employ another rationale of contrasting and inference and are covered in Section 3.04.2. Multiple-group extensions to this design are covered in Section 3.04.5.3. Designs two, five, and eight have the most desirable properties: they implement randomization, repeated measurements, and control groups, with multiple observations additionally available in the last one. These designs are discussed in Chapter 4, this volume. From the preceding, it is clear that the rightmost column contains three nonequivalent group designs which do implement multiple group comparisons. Design three, however, is subject to the same reservations made for designs one and four. It lacks both randomization and pretesting as an approximation to the same end. Therefore designs six and nine, when used with appropriate care and caution, permit the testing of causal hypotheses, with causality being conceived as in Section 3.04.3.

The worked example is continued with aspects of design

> In quasi-experimental design, the treatments to be compared serve as independent variables and experimental groups are built by assigning subjects to treatment conditions by nonrandom procedures. In the worked example study by Yung and Kepner (1996), the treatment factor comprised stretch release (SR), tense release (TR), and cognitive relaxation (COG) as well as a placebo attention group and a test-only control group (TOC) that remained wholly untreated. The placebo group was given a medicament by a physician with the ruse that it would reduce blood pressure in order to control for positive treatment expectancy effects. The control group were given pure assessments of their blood pressure to control for effects of the measurement process itself. Systolic and diastolic blood pressure as well as heart rate were chosen as dependent variables, entailing a multivariate setup for subsequent statistical analysis. All subjects were measured repeatedly several occasions (multiple baseline readings, with assessments before and after trial, follow-ups), which gives a multiple-treatment–multiple-control extension of design six in Figure 2.

Note that the study outlined above does in fact realize most of those items that make up the following sectional structure: conduct of pretests, multiple observations, different forms of treatment, different forms of control groups, and, introduced *post hoc* by means of statistical analysis, even combination of different designs.

3.04.5.2 Using a Pretest

3.04.5.2.1 Using pretest as a reference for gain scores

The major step from design three to design six clearly lies with the introduction of pretesting, seemingly indicating analysis of change. A natural concept of an ES would derive by subtracting pretest averages from post-test means and normalize the result with respect to a control group for a comparison. There has been extensive work on the question whether or not to use difference scores as an estimate of ES. Some main issues addressed in this context comprise the fact that difference scores (i) carry the unreliability of both their constituents, (ii) depend on correlation with initial (pretest) scores, (iii) depend on scale characteristics, and (iv) are subject to regression towards the mean. Various alternative techniques have been proposed among which are (i) standardizing prior to calculating differences, (ii) establishing "true" difference scores (Lord, 1963), (iii) using regression residuals (Cronbach & Furby, 1970) and, (iv) most commonly used, regression adjustment by means of analysis of covariance. Further, in terms of mathematical models, specification of correlation structure for error components of total scores, decomposition of error itself into various time-depending and static components, as well as the formulation of model-fit criteria and appropriate statistical testing, with serial dependence of data contradicting the "usual" (IIND) assumptions on error terms, are of major concern when analyzing change. These items denote not mere problems of statistical theory, but reflect substantial problems about a concept of empirical change. There is, however, no concern about all the complications that arise when trying to measure change but with the logic of design. For an introduction and further reading on the above issues, see Eye (1990), Diggle, Liang, and Zeger (1994) and for special topics as indicated Kepner and Robinson (1988) and Thompson (1991) (ordinal measures), Hagenaars (1990) and Lindsey (1993) (categorical data), Christensen (1991) and Toutenburg (1994) (generalized linear models), Vonesh (1992) (nonlinear models), Farnum and Stanton (1989) and Box, Jenkins, and Reinsel (1994) (forecasting), Petermann (1996) and Plewis (1985) (measurement).

3.04.5.2.2 Using pretests as approximations to initial group equivalence

In Section 3.04.2 the concept was introduced of an ES as the observable and testable formulation of what is sought in experimentation: effects. As can be seen from Figure 2, repeated measures are not strictly required to demonstrate effects. As is the case in design three differences may be observed in dependent measures across independent samples that underwent two different treatments (or none for a control) and state that one group scored higher on the average (this being favorable). Drawing any inferences or preferring this treatment over the other (or none) as a result of such a post-test-only design would rest entirely on the assumption that groups were equivalent with respect to dependent variables prior to treatment application. In "true" experiments, random subject assignment and/or large samples may be relied upon to justify this assumption, but in quasi-experimental design performing a pretest is strictly required to obtain meaningful results. One still does not need to take gain scores or measures of different growing rates as a base for an effect size. In Section 3.04.2, they were not. But post-test differences can only be interpreted as monitoring effects when initial group equivalence is given as a common ground for comparison. As a consequence, subject assignment in quasi-experimental design is based upon techniques that require a pretest (see Table 2).

3.04.5.2.3 When not to use a pretest

Research situations can be imagined where conducting a pretest may not be recommended for even stronger reasons. Suppose that the phenomenon in question is likely to change qualitatively rather than quantitatively. A pretest would then presumably first measure something different than post-test. Second, a pretest may interact with treatment by differential sensitization (see factors of internal validity) or by producing such bias that results could not sensibly be attributed to treatment anymore (e.g., when using attitude tests). Third, retesting may be impossible because testing can only be set up once on the relevant variable because measurement must be assumed to distort or annul the phenomenon, or because no parallel form of a test is available. In such cases, the use of a proxy variable might be considered which, measuring something different but conceptually related to post-test criteria and, thus, (hopefully) being correlated to it in the statistical sense, serves as a substitute for evaluating initial group equivalence as a prerequisite for interpreting post-test differences (Rao & Miller, 1971). In extreme cases, when any kind of pretesting, be it on behalf of proxies or using the post-test instrument, seems impossible, using separate samples "from the same population" for pre- and post-test may be in order. From the preceding it is clear, however, that this variant of the basic design (six) provides a very weak basis for inference. Selection cohort designs as proposed in Cook and Campbell (1979) can be understood as a conceptually improved (while more demanding) extension of separate sample designs. When using self-selected samples it is obvious that subjects collected from cohorts that fall into place with regular periodicity because of characteristics of natural environment can be considered more alike than separate samples with obscure nonrandom selection processes. As this is most typically the case for institutions with cyclical (e.g., annual) turnover, like schools, such designs have been labeled "recurrent institutional cycle designs" (Campbell & Stanley, 1963).

3.04.5.2.4 Outcome patterns

It is trivial to state that informational complexity of outcome pattern depends on the factorial complexity of design. It should be borne in mind, however, that sophisticated group and treatment structures do not necessarily entail higher levels of information or yield better causal models of a post-test. For example, the higher an order of interaction is allowed in fully crossed factorial designs, the less readable will be the results obtained and interpretation will be difficult. Pedhazur and Pedhazur (1991) give examples of how adding predictors to regression equations alters coefficients of former included predictors and changes overall results. Though the foregoing statements about validity and control may suggest a kind of "the more the better" strategy when designating independent and dependent variables for a design, the ultimate purpose of all modeling, simplification, should be recalled. The ultimate prerequisite in modeling, however, is of equal importance to the same end: unambiguous specification. Design six, for instance, when including two pretest occasions and being carried out on near-perfectly matched groups of sufficient size with near-constant treatment integrity, clearly outperforms a time series extension of the same design (see below) with uncontrolled subject attrition and carry-over effects.

A naturally expected, and in most cases desired, outcome of basic design six would obtain when the average post-test response of the treatment group is found to differ significantly in desired (hypothesized) direction from the control group post-test scoring, given pretest equivalence and given zero or nonsignificant trend in the control group pretest–posttest mean scores. But there are several variations of that scheme, largely due to selection–maturation interaction, regression artifacts, and scale characteristics (see Table 1). Cook and Campbell (1979) discuss at length such different outcomes of design six in its basic form (parallel trend lines, differential growing rates for groups, nonconstant controls, controls outperforming cases, treatment leading to post-test equivalence, trendline crossover ["switching means"]). Testers should not, however, as might be suggested by these authors and the foregoing presentation of all those threats to validity, too readily attribute findings not in line with expectations to design misspecification, artifact operation, and limitations of diagnostic devices. It is true that there is always our obligation to evaluate and justify the whole procedure of research instead of its findings only. But having revised the process of hypotheses derivation that leads to design, and to data as a result, and having confirmed derivation validity to a maximum extent attainable within the limits offset by a concrete research context, there should be no complaints about reluctant and unruly reality.

3.04.5.3 Using Multiple Observations

It is obvious that design nine is but a generalization of standard design six, taking advantage of multiple observations pointed out above, and being subjected to the flaws of multiple repeated measurements. While the extension is straightforward as regards the logic of contrasts (the rationale for multiple group comparisons), the notion of an effect and according ES is more difficult to define. Time series analysis is usually carried out to detect and analyze patterns of change over time or to build models for forecasting. Multiple group comparisons enter when chosen to define an effect in terms of different time series evolution for cases and controls, conditional on a preintervention phase (baseline) and triggered by differential onset, intensity, and duration of treatment. Two major problems must be considered, then: first, how should treatment and observation phases be scheduled in the course of the whole study in order to set contrasts for obtaining effects while accounting for time-relevant threats to validity (see Section 3.04.5.4 using multiple forms of treatment); second, how to statistically analyze serially dependent data and interpret contrasts in the data in terms of within-subject (within-group) vs. between-subject (between groups) patterns (see Section 3.04.6).

The major benefit of using multiple observation has been presented in Section 3.04.5.1 (control for maturation and regression). Adding a control group further permits control of history and instrumentation for there is no *a priori* reason to suppose that untreated subjects experienced different environmental conditions during the study or that they should react differently to repeated measures. While nonspuriousness of treatment effects justifiably may be assumed by reference to significantly different pretreatment levels or increased/decreased slope of baseline, temporal persistence of effects can never be assured without comparison to an untreated control group.

As it is intended to dedicate the section on analysis mostly to handling design six and its nontime-series (i.e., simple pretest–post-test) extensions, a few words on statistical analysis of time series experiments are in order here. For more detail see Glass, Wilson, and Gottman (1975), Gottman (1981), and Lindsey (1993). Comparisons of intercepts (level), slopes (trend) and variance (stability, predictability) are mostly used for contrasting pre–post phases. Note that effects in time series designs need not instantiate immediately with treatment application and pertain. Impact of treatment may be delayed, with gradual or one-step onset, and various forms of nonconstancy show up over time (linear, nonlinear, or cyclic fading or gain, etc.). But such rather sophisticated parameters of time series data will only be used rarely for ES definition: statistical tests for directly comparing oscilation parameters or analytically derived characteristics like assymptotic behavior (e.g., speed of point convergence) are not readily available. While most one-sample time series parameters of interest to researchers concerned with intervention analyses can be identified, estimated, and tested for by transfer function models, between-sample comparisons often reduce to fitting an optimal model to one group and observing that fit indices decrease when obtained from application of the same model in another group. Cross-series statistics are, after all, hard to interpret in many cases (they require consideration of lead-lag relations, etc.). For an introduction to interrupted time series analysis for intervention designs see McDowall, et al., (1980) or Schmitz, (1989), and illustrated extensions to nonlinear and system models are presented in Gregson (1983).

3.04.5.4 Using Different Forms of Treatment

In this section concerns about implementing different forms of the same treatment instead of adding treatments like in a factorial design will be discussed. In basic pretest–post-test designs of type six, treatment is applied only once. Hence, variations concern application or removement only. Graduation in treatment application or withdrawal calls for multiple groups to undergo such graduation. This would be achieved, in concept, by stacking k–1 pretest–post-test designs without a control group over standard design six for k levels of treatment to be tested. The resulting model would conform to standard one-way analysis of variance for differences scores with a fixed or randomly sampled treatment factor (see Section 3.04 .6). In time series designs, however, some more challenging variations are at hand that further increase validity and clarity of inference, if properly implemented. Figure 3 gives an overview.

Design 10 replicates design four, with treatment removed in the second block in order for this block to serve as a "same-subjects" substitute for an otherwise nonavailable control group. Careful consideration must be given to the following questions:

(i) Are treatment effects of transient nature and be made to fade out (it is supposed, generally, that persistence of intervention effects is desired)? Ethical concerns, financial questions and potential attrition effects could be added to hesitations about mere feasibility of such designs.

(ii) Is it reasonable to expect that average scoring will return to a near-baseline level after removal of treatment?

(iii) Will it be expected that, after reintroduction of treatment as in design 12, effects will reinstall the same way (delay, size, stability, etc.) as in the first turn? (It is supposed that the reader is acquainted with general replication effects in experimenting like learning and resentment.) Then, and especially in case of high-amplitude treatment and obstrusive measurement, construct validity will be seriously affected.

If answers are favorable to these concerns then the designs that are particularly useful in evaluation of recurrent intervention components can be disposed of. Next should be considered the reversed treatment nonequivalent control design 11 with pretest and post-test. Cook and Campbell (1979) suggest that this design outperforms standard design six as regards construct validity since a treatment variable has to be specified rather rigorously in order to determine its logical reverse and an operational mode for it to be applied. Nevertheless the additional use of a wholly untreated control group is strongly advised in order to arrive at clear-cut results, in case trend lines do in fact depart from (assumed equivalent) pretest levels in opposite directions but in slopes that differ with respect to size and significance. Including a common reference for contradicting provides a very strong basis for inference. Finally design 13 (interrupted time series with switching replications) is considered. Due to delayed treatment application, one group can always serve as a control during treatment periods of the other ("reflexive controls," Rossi, Freeman, & Wright, 1979; "taking-turn controls," Fitz-Gibbon & Morris, 1987). The particular strength of this design lies with its capability to demonstrate simultaneously effects in two different settings and points of time with greatest parsimony. Still it is possible to overcome most threats to validity that are faced when using the above designs.

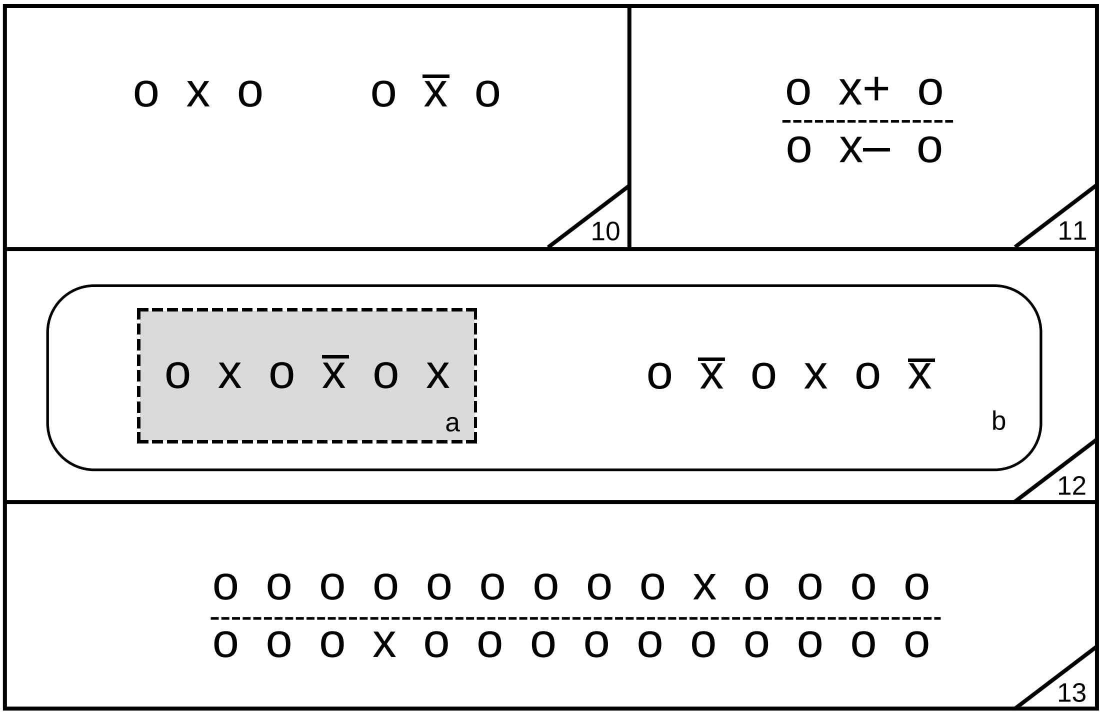


Figure 3 Designs using different forms of treatment.

3.04.5.5 Using Different Forms of Comparison Groups

It has been pointed out frequently that to use a control group is indispensible as a baseline for comparison in most cases of quasi-experimental research, and highly advocated in any other. Effects should be demonstrated by either relative change or post-test difference to rule out alternative explanations besides treatment impact. While this is widely agreed, there has been some controversy as regards various qualitative characteristics of controls. Are controls really untreated as assumed for inference? How can control groups be maintained (they do not receive, after all, any benefits of treatment)? Is there such a thing as placebo treatment? Do waiting groups (subjects scheduled for subsequent cycle of treatment, see design 13) differ in any substantial respect to wholly unaffiliated pools of control? In many cases the nature of a control group is determined simply by contextual factors like availability in terms of total number of subjects, financial resources, ethical considerations, or the time horizon of the study. While "real" control groups receive no treatment at all, placebo groups receive only irrelevant treatment. Conceptually, there are two forms of such irrelevance. In the first case, intervention neither in theory nor in statistical terms relates to the treatment variable of interest and is only meant to minimize motivation effects like resentful demoralization. A second version refers to treatments that in fact can be, or even are, expected to contribute to effects by operating through subjects' expectancies and external attributions that are hypothesized to go along with actual treatment. Perhaps the most prominent example is medication with a sugar pill. Note that such placebos work on psychological grounds and usually are implemented to separate such effects from "real," physical, or pharmacological treatment. As a consequence, it might be difficult to define a psychological placebo in psychotherapy research. For further detail on the issue of placebo groups, see a well-received article of Prioleau, Murdock, and Brody (1983), defending admission of such placebo treatment, and subsequent peer commentaries in *The Behavioral and Brain Sciences*. Waiting control groups differ from untreated groups in that they must be supposed to expect benefits from treatment to come. As a consequence, after assignment, such subjects may show more sensible behavior in any respects related to health and well-being or more medical compliance (thus "raising" baselines into trendlines). Waiting groups are, however, easiest to recruit and maintain, they naturally fall into place when treatment cannot be delivered unlimitedly, and there is no way of avoiding selection for admission. Still another concept of a control group emerges when using qualitatively different treatments in comparison groups, that is distributing treatment across groups. A way of treating a disease might, for instance, to compare against current or standard treatment, thus highlighting the relative merits of the new and saliently different features of the innovative treatment. Technically, within the ANOVA framework introduced below, treatment would represent a fixed factor with more than two levels (treat1, treat2, etc). It is clear that adding a further untreated control group is still preferable (see Section 3.04.5.6).

3.04.5.6 Using Combinations of Different Designs

There are three convincing arguments for combining designs. First, combining complete designs rather than extending one of their internal features (as discussed in above subsections) will generally enhance control. Second, broadly defining designs themselves as methods and using different methods and research plans in addressing the same question and phenomenon will always decrease monomethod bias and increase both construct validity and generalizability of results. Third, combining designs offers refined testing of hypotheses. For example, in Section 3.04.5.4 it was proposed, to multiply stack design four over design six. Consider now the application of different dosages of a drug as treatment variable. Given initially comparable groups (in the present, quasi-experimental sense), trend hypotheses about dosage could even be tested. Also, integral features of basic designs as depicted in Figure 2 may be tested for their mediating effects. For an example, if design six is stacked over design three a composite design is obtained that allows for separation of pretest and treatment effects and is named after its proposer Solomon (1949). Note that there are two fully crossed factors: whether treatment is applied or not (case–control factor), and whether pretesting is administered or not. This design may now be conceived as factorial (see Chapter 3, this volume) and an analysis of the main effect of treatment made (disregarding effects of pretest sensitization and the like), main effects of pretesting (effect obtained without regard to treatment), and interaction (treatment effects depend on pretest). If statistical testing has determined that such interaction is present, consideration of the main effects due to one sole factor (e.g., treatment) is sure to yield misleading results and inferences. But the latter is always true in cases where any design is used that both lacks randomization and pretest. As a consequence, this rather sophisticated design is mostly applied in research situations that allow for randomization. Trivial as it may seem, another way of combining designs lies with replicating the whole basic design using the same samples and measurement occasions by simply obtaining multivariate measures of posttest indicators and, thus, testing multiple predictions concerning the same outcome criterion.

3.04.5.7 Regression Discontinuity

As if to provoke further discussion in order to put an end to presumed underutilization of regression discontinuity (RD) designs, Trochim (1984) stated that RD "is inherently counterintuitive . . . not easy to implement . . . statistical analysis of the regression discontinuity design is not trivial . . . [there are] few good instance of the use" (pp. 46–47). So what is the point in these designs? In structure and objective, RD designs conform to the layout of design six. The major difference lies with assignment policy: while randomization is believed to guarantee fully equivalent groups (in the long run, that is) and pretest equivalence in nonequivalent group designs assures comparability with respect to the variables in questions only (leaving obscure presence and influence of other selection processes), it is maximum nonequivalence that serves as a rationale of regression discontinuity designs. This is achieved by ordering subjects according to their scores on the continuum of a pretest scale and subsequently defining a cut-off point for division into further subsets to be assigned to different conditions. Most commonly, subjects scoring below the cutting point would then be assigned to one group, subjects scoring below this point to another. If a "sharp" cut-off point is not desirable on theoretical grounds or because of known unreliability regions of scales, a midscale cut-off interval might be used instead, with interval width depending on estimates of measurement error similar standard deviation. Subjects within this range would then be assigned randomly to either treatment or control group condition. While it is true that the process of subject selection is still only imperfectly controlled because merely one factor (the dependent variable) is accounted for, it is perfectly known since being specified entirely by the researcher. It is clear that, in order to prevent cut-off point selection being rather arbitrary, strong theoretical grounds or consent on practical concerns (limited therapy resources, etc.) are called for.

Basically, analysis of RD designs means testing hypotheses of equality of regression equations across groups similar to analysis of covariance. The objective is to ask whether the trend or regression line obtained from analysis of the treatment group pretest and post-test scores is displaced significantly from the respective control group regression line. If displacement is due largely to greater (or lesser) intercept, while slopes are statistically equal (parallel line regression), a main efect has been successfully demonstrated. Stated differently, with no effect present, a single regression line would equally fit scores of both treatment and comparison group and, as a consequence, a trend in the treatment group could be predicted from the control group scores. Interaction effects are revealed by discontinuity in slope of regression lines at cut-off point. Note that, technically, regression need not necessarily be linear but can include parameters of any order, but that extrapolation of a trend line becomes extremely difficult then and often leads to false conclusions about effects (see Pedhazur & Pedhazur, 1991). These problems notwithstanding, more frequent use of these designs is recommended. In many intervention research contexts, subjects not only are in fact but also should be assigned to either treatment or control groups by need or similar, perhaps medical, criteria related to both treatment and outcome.

3.04.6 ANALYSIS

Having successfully derived and implemented a multiple group comparison design there is now a need to fit a statistical model to the data obtained in order to test the hypotheses on the "final" deductive level in the process model of empirical research (Figure 1). In particular, there is an interest in deriving ESs and whether they are different from zero. Note that from an epistemiological point of view, use of a different statistical model is made than observational methods (see Section 3.04.1.2). Here, models are considered as mere tools for hypotheses qualification and inference and are not of contentional value besides some implications of their structural assumptions (like additivity, linearity, etc.). Analysis of nonequivalent group designs is achieved in three major steps. First, the overall rationale of analysis is introduced by borrowing from the theory of generalized linear models. Second, its specification language is used to acquaint the reader with a system of models that indeed is a superset to nearly all models applicable in this context. Third, a closer look is taken at a subset of models that are most commonly employed in treating standard design six, namely analysis of variance with or without adjusting for a covariate and its respective conceptual analogies when ordinal or categorical data have been obtained. Since there are many textbooks on statistical data analysis that cover technique in detail, attention is drawn merely to the principle and major formulae and dispensed with (references are given, however).

It is important to understand that until now discussion has been located entirely in the realm of logic. Nothing has been implied as regards scale and complexity of measurement and data. The point is that anything can be stored in O (Figures 2 and 3) and that structural complexity of whatever resides in this data aquisition box is logically independent of complexity in design structure. Enlarging designs by stacking subelements simply adds data boxes and obtains lots of data and can sometimes lead to technical difficulties in statistics, but both of these features should not complicate the idea or inference behind the material. In fact, there is only one condition: statistical parameters obtained from the data must be comparable on formal (i.e., mathematical) grounds (distributions, standard error of estimate, etc.). Now dominance of comparison-of-means-style models is readily explained: differences in means of normally distributed variables again follow normal distribution, and departure from zero is most easily tested using direct probabilities. In essence, value and standard error of any parameter's estimate should be determined and related to each other (e.g., in a ratio, giving standard t-test in case of metric dependents) or to another pair of parameters (e.g., in a double ratio, giving standard F-test, respectively). But there are many other ways besides of comparing distributions, some less strict but more straightforward or creative.

Why not obtain entire time series for one single data box in a multiply repeated measurements design? A time series model may be fitted to data at each occassion resulting in microstructural analysis. Stated differently: time series information has been condensed into some quantities that now enter macrostructural analysis reflecting design logic. Here, one might compare such aggregate measures in a pre–postfashion analysis like in standard design six, thus evaluating treatment impact by relative change in parameters of local change. Other studies involve entire structural equations systems in a single data box, constructed from covariance structure in multivariate data obtained at one occassion (Bentler, 1995; Duncan, 1975; Möbus & Bäumer, 1986; Jöreskog & Sörbom, 1993).

Most textbooks on the statistical analysis of experiments focus on analysis of variance and associates. While preference for models assuming variables on an interval or rational scale is perfectly understandable from the researchers point of view, it is felt that there is a rationale of testing that allows for far more variety. Appreciation of this variety is badly needed in order to be able to choose an analysis model for the design present, thus preserving the rather deductive idea of the process model in Figure 1, instead of being forced to the contrary: adapting design and idea to some analysis model readily at hand from common textbooks. Variety need not imply incomprehensible diversity if there is a model rationale. Here, the rationale states: all analysis, excepting some tests for ordinal data working on special ranking methods, boils down to regression. This holds true even in cases where it might not be expected that a regression structure presents at first glance (joint space analysis in multidimensional scaling, etc.). Most important, it is also true for analysis of variance and companions since these models can be written as regression equations of metric dependent variables on a set of coded vectors. These dummy variables, then, represent treatment in all its aspects (intensity, frequency, schedule of application, etc.). Encoding logic of designs into what is now called a design or hypotheses matrix for statistical analysis certainly is an art of its own (for an introduction, see Kerlinger (1973), or Pedhazur & Pedhazur (1991)). But here, regression stands for a whole family of models obeying a certain relational form. Thus, the rationale translates to concrete statistics by proposing that all variable relations (and contrasts are just a special relation) be specified in the form $y = f(x, \beta, e)$, where y denotes a possibly vector-valued set of responses (dependents) and x denotes a set of explanatory variables (independents, respectively) that are used to approximate the response with determinable residual or stochastic error e. A set of coefficients β quantify the intensity of an element of x (which can be interpreted as effect information), these parameters are estimated conditional to the data by minimizing a quality function ("least squares," "$(-2)*$maximum likelihood"). Finally, $f(.)$ denotes a characteristic link function that relates the explanatory or predictive determistic part of the model and error component to the response. Mostly used for this purpose are identity link (giving standard multiple regression), logit link (for binary response), and logarithmic links (leading to regression models involving polytoneous categorical data). In this way of thinking, the data are thought of as determined by the model but jammed by additional random error. Note that "error" does not denote anything false but is meant to incorporate, by definition, all factors in effect that remained unspecified or did not explicitly enter the model (i.e., remain uncontrolled).

To sum up, ingredients of a model are variables, parameters, a link function to algebraically interconnect all these, and an estimation strategy to optimally fit the resulting model to the data. The point in mapping most different ideas and objectives into a common-models structure is variable designation: using intensities can still mean single-attribute utilities, attitude strength, blood pressure. But $y = f(x, \beta, e)$ is too much in the abstract to be of use for this purpose, and even giving an outline on mathematical formulation and derivation of some less hard-to-handle submodels or estimation techniques would be beyond the limits of this chapter. For an advanced reading and a complete build-up of generalized linear model theory and practice see Arminger, Clogg, and Sobel (1995), Christensen (1991), and Diggle et al. (1994). But model specification terms summarized in Figure 4 can be used to figure out the greater proportions of the generalized linear model. Note that not everything goes along with anything else when crossing items on the utmost right side and that some models use parametrization strategies that do not satisfy the condition of formal comparability of parameters across groups. What is required now is careful examination of the nature of the variables and the justifiability of assumed form of relations among them. Never follow the impression possibly implied that all it takes is simply picking up a model from the scheme and applying it to the data if the marginal parameters are met. While it is true that with the exceptions mentioned above almost any statistical model of interest for analysis of designs can be integrated in or extrapolated from the generalized linear models scheme, the fit of design and analysis model is never guaranteed from this alone.

Several submodels can be located from that scheme that are most commonly used in analyzing experiments of type three and six (in Figure 2) and that may now be arranged in a more readable tabular system. If groups or discrete time are assumed for a single independent variable of categorical nature, and an arbitrary scale for a single dependent manifests, variables measured in discrete time and everything else in Figure 4 is dispensed with, the following table results (Table 3). In view of practice, that is, software, some submodels present not as rigorously special cases of the Generalized Linear Model (though they all can be specified accordingly), but rather as "standalone" implementations of tests. They serve the same purpose and are integrated in all major statistical software packages.

Figure 4 Building blocks in the Generalized Linear Model (GLM).

Table 3 Common models for analysis of designs three/six.

Idea of effect	*Independent (group-time)*	*Scale of single dependent*	*Analysis/test*
Simple change	One sample pre–post	categorical	McNemar test
		ordinal	Wilcoxon test
		metric	dep. t-test
	One sample k times	categorical	Cochran Q-test
		ordinal	Friedman test
		metric	One-way ANOVA rep. meas.
Post-test differences	Two samples	categorical	Simple χ^2
		ordinal	Mann–Whitney test
		metric	indep. t-test
m samples		categorical	Logit/Loglinear models
		ordinal	Kruskal–Wallis test
		metric	One-way ANOVA
Relative change (interaction)	m samples k times each	categorical	Logit/Loglinear models
		ordinal	Loglinear models
		metric	m-way ANOVA rep. meas.

Further insight can he gained by the introduction of the analyses of variance. These models are considered the standard for analyses of multiple group comparison designs, but there is no hope of covering its various features and the richness of its submodels in detail. For the time being, do not bother with the distinction of fixed-effect, random-effect, and mixed models but with the rationale of analysis (for details, see Hays, (1980). Especially in the case of repeated measurement models, there are, however, some ideas and assumptions that must be understood before actually using these techniques, most prominent and important among these are: heteroscedasticity, additivity, orthogonality, balance, degrees of freedom, compound symmetry sphericity. In addition, further precautions as regards covariance structure are in order when extending the model to multivariate analysis of several dependent variables. For advanced reading on these topics whose consideration is indispensible for enhanced statistical conclusion validity, see Toutenburg (1994) or Christensen (1991).

Consider that response data $\vec{\boldsymbol{y}} = [y_1 y_2 \ldots y_m \ldots y_M]$ on M dependent variables are obtained on interval-scale level for $k = 2 \ldots k \ldots K$ samples of equal size; for convenience, $n = 1 \ldots i \ldots N$ at $t = 1, 2 \ldots t \ldots T$ occasions. A categorical independent variable (or factor $f1$ denoting treatment(s) $f1 = (f1_1, \ldots, f1_{\bar{k}}, \ldots, f1^K)$ has been realized at least twice in one sample or independently across different samples at any occasion $1 < t < T$. Treatment $f1_{\bar{t}}$ denotes "no treatment" for implementing nonequivalent control group(s). If $\hat{\boldsymbol{y}}$ offers data on more than one dimension ($M > 1$), multivariate analysis (MANOVA) is called for, if it reduces to a scalar ($M = 1$) but extends in time ($T > 1$), univariate repeated measures ANOVA is applicable. For $M = 1$ and $T = 1$, effects are evaluated using a post-test-differences-only-given-pretest-equivalence rationale as presented in the first row in Table 3 (performed with a t-test for $k = 2$ both uni- and multivariate and any (M)ANOVA for $k > 2$). With repeated measures carrying effect information ($T > 1$) as it holds for both other rationales, data setup is a bit more sophisticated. Common software packages usually take repeated measures of one variable for separate variables (maybe with the same root name: p.ex. *out*1 *out*2 *out*3 … for criterion variable *out* at three occasions). It follows that a multivariate data setup of the input data matrix is required. Note that when more than one genuine variable besides *out* enters analysis, a doubly multivariate procedure is called for. Stated differently, M variables are to be analyzed whose respective T time-dependent realizations are coded as T different variables, giving $M \times T$ data columns in a typical data entry spreadsheet of minimal logical dimension $(N * K) \times (M * T)$ since data are obtained for K groups of N subjects each. This holds true, so far, for any one-way (M)ANOVA with a k-level treatment-factor, affecting one or more metric dependent variables. In most instances, however, it is likely that this root design will be extended by introducing:

(i) further experimental factors subject to manipulation (e.g., single vs. group therapy),

(ii) further cross-classifying factors that fall into place from basic sample analyses (e.g., age, sex, hospitality, etc.),

(iii) further metric time-invariant covariates (e.g., onset of disease, initial dosage of medication), and

(iv) further metric time-varying covariates (e.g., ongoing medication).

The general idea of analysis of variance is rather simple: if means between k groups and/or t occasions differ, and this is what is called an effect, roughly, then they are supposed to vary from the grand mean μ obtained from collapsing over all $M \times K$ data points disregarding groups and treatments or collapsing over occasions giving the grand mean as a "no-change" profile of t equal means. If they do vary significantly then this variation should be to a certain proportion greater than variation present within groups (i.e., with respect to the mean in a group). More specifically, a partitioning of total variance found in the data matrix into (at least) two components is attempted: variance of *groups'* means reflects the systematic ("causal model") part that is solely attributable to variation of treatment (be it in time or across groups), whereas variance of subjects' measurements within a group is generated by interindividual differences (i.e., violation pretest-equivalence or lack-in-treatment integrity) and is therefore taken as an "error term" against which the other part must be evaluated. Remember that the ratio of two variances or two sums of squares divided according to degrees of freedom constitutes on F-value when certain assumptions on data (Hays, 1980) are met: statistical significance is readily tested for. In this way, model variance due to effects, possibly containing interactions when more independent variables are present and error variance due to anything else, add up to give the total variance (assuming a fixed effect model). In the case of repeated measures analysis, there is also variance among t different measures of a single variable within one subject. To sum up: three main effect sources of variation are accounted for by standard ANOVA models:

(i) differences between individuals, to be further decomposed into differences between k groups (disregarding the individual by taking means and thereby constituting a "true value" outcome measure for this treatment) and differences between subjects within a group, obtained from subtracting the individual's measure from the group mean. In analyses with no repeated measures factor present, these differences contribute to error variance against which the first kind of variation is evaluated. In the case of f-way ANOVAs, interactions of independent variables (factors) must be taken into account as well.

(ii) Differences within repeated measures of a subject and according interactions with factors varied between groups in f-way analyses. This variation may be further decomposed into three sources: a main effect of retesting (supposed to be present in each subject's profile over time), an interaction of treatment and retesting, and differential reactions to retesting (specific to each of the subjects). In case of analyses with no between-factors present, the latter source of variation is taken to contribute to residual variance. In multiway repeated measures analyses of variance, determination of appropriate components for a F-ratio in order to test for statistical significance of a factor or an interaction of some factors, can be very complicated; excellent advice is given in Bortz (1993).

For design six, a differential change would be required for an effect by testing the interaction term of a repeated measures "within" factor and the case–control "between" factor for significance using the appropriate F ratio. Change takes place but in different directions (or none) depending on whether receiving treatment or not. Suppose one group of aggressive children received behavior modification training while another group of equal size is still waiting for admission and thus serves as a control group. Both groups are considered equivalent on the dependent variable of interest beforehand. Take it that $t = 3$ measures on each of $N_1 + N_2$ individuals in $k = 2$ groups: pretest, post-test after training, and a follow-up retest six months after intervention to estimate the stability of possible effects. Formally expressing the above sources of variation in a structural model for the individual measure, as is common for GLM submodels, and dispensing with explicit notation of associated dummies for discrete independent variables leads to:

$$y_{ikt} = \mu + a_k + \beta_t + (\alpha\beta)_{kt} + \gamma_{ik} + \epsilon_{ikt}$$

where α_k refers to effect of being in either treatment or control group, β_t refers to differences solely attributable to time or change, $(\alpha\beta)_{kt}$ stands for the interaction of both main effects and thus denotes differential change as sketched above and in greater detail in Section 3.04.1.3, γ_{ikt} refers to a random (= erroneous) effect of a single subject i in the kth kind of treatment (training vs. control, in the case present), maybe for individual specific reaction types to either form of treatment at any occassion, and ϵ_{ikt} accounts for anything not covered by the model (error term).

For full coverage of mathematical assumptions underlying this model, see Toutenburg (1994). As mentioned before, statistical hypotheses are formulated as null hypotheses conjecturing "no effect" of the according term in the model. In addition, for the present example, effects of several levels of an independent variable are required, coded by an according contrast in the hypothesis matrix (see above), which add up to zero. Hypotheses testable in this model include:

H_0: $\alpha_1 = \alpha_2$
There is no difference between treatment and control group with respect to the outcome variable (dependent), disregarding point of time of measurement. More generally speaking, such between hypotheses state homogeneity of measurement levels in groups. Note that no differences at pretest time are expected. Moreover, differences possibly present at post-test time (near termination of intervention) tend to attenuate up until the follow-up testing. It is not known whether group differences were at maximum by consideration of this main effect of group membership alone.

H_0: $\beta_{c1(t)} = \beta_{c2(t)}$
specific formulation depending on contrasts $c(t)$ for time effects.There is no overall change between occasions disregarding group membership. Again more generally speaking, the hypothesis states homogeneous influence of time effects in the course of experimentation. Considering this time main effect alone, it is known that whatever change occurred applied unspecifically to both groups and can therefore not be attributed to treatment. Obviously, this effect does not carry the information sought. When certain assumptions on covariance structure in time are met (sphericity condition, see above), a $t-1$ to orthonormal linear contrasts may be used to evaluate change at certain periods using univariate and averaged tests. These assumptions assure, roughly speaking, that present differences are due to inhomogeneity of means rather than of variances (for details, see Toutenberg, 1994). Major software packages offer correction methods to compensate for violations of these assumptions (e.g., by correcting components of the F-test) or have alternatives available.

H_0: $(\alpha\beta)_{ij} = 0$
This hypothesis states parallelism of progressive forms in groups or, equivalently, the absence of differential change. If this hypothesis can be rejected, there is an interaction of treatment and the repeated measurement factor in the sense that (at least) one group apparently took a different course from pretest to post-test and follow-up as regards the outcome criteria. This is precisely what was presented as the standard notion of an effect in Section 3.04.3. Such a change can be attributed to treatment because the overall effects like common linear trends and so on, have been accounted for by the time of main effect. In more complex cases, there may also be interest in differential growth rates or whether one group arrived sooner at a saturation level (suggesting earlier termination of treatment).

Actual testing of these hypotheses might be performed using "means models" available with the (M)ANOVA procedures or by parameterizing the above equation to fit the general linear model regression equation with identity link. In essence, this is done by building a parameter vector $\boldsymbol{\beta}$ of semipartial regression coefficients from all effects noted (μ, α_1, … α_{k-1}, $\beta_{c_1(t)}$ … β_{ct-1}), associated by the corresponding hypotheses matrix X (made up from coded vectors of contrasted independent variables) and an additive error term. This right-hand part of the equation is regressed on to the vector $\vec{\mathbf{y}}$ giving a standard Gauss–Markov–Aitken estimate of $\beta = (X'\Sigma^{-1}X)^{-1}\, X'\Sigma^{-1}y$ from least squares normal equations. A typical printout from respective software procedures includes parameter value, associated standard error, and t value, confidence limits for parameter estimate, η^2 effect size, F-noncentrality parameter, and power estimate. When interpreting results, remember that an effect is conceptualized as a difference of respective group (= treatment) mean from the grand mean, and that effects are usually normalized to add up to zero over all treatments (for details and exceptions, see Hays, 1980).

Analysis of the worked example study was carried out as follows:

> A one-way ANOVA with repeated measurements was used to test statistical significance of recorded difference in three dependent variables for five experimental conditions at pre, post, and follow-up occasions. There was no significant overall main group effect. Only systolic blood pressure was found to differ across groups at follow-up time with greatest reduction present in a comparison of TR to TOC. Group-time-interactions for testing differential change were carried out by an ANOVA using repeated contrasts (pre vs. post; post vs. follow-up). Systolic blood pressure decreased significantly over time in all relaxation groups and the placebo group, but not in the control group. TR muscle relaxation showed greatest reduction of diastolic pressure, whereas SR and COG significantly lowered heart rate. Pooled treatment effects were evaluated against nontreatment groups by special ANOVA contrasts, showing significant reduction in systolic pressure when compared to control group and significant reduction in diastolic pressure when compared to the placebo group. There were no effects on heart rate in comparison to either one of the nontreatment groups. The results indicate a strong placebo attention effect. It is suggested that independence of heart rate and significant blood pressure reduction is in line with the findings in the field.

With additional restrictions put on Σ, this rationale of testing easily extends to multivariate and doubly multivariate cases (Toutenburg, 1994). Also, there is much appeal in the idea of comparing groups on entire linear systems obtained from all measured variables by structural equations modeling (SEM; see Duncan, 1975). Here, measurement error in both independent and dependent variables is accounted for explicitely. For an introduction to multiple-group covariance structure analyses and to models additionally including structured means see Bentler (1995), Möbus and Bäumer (1986), and Sörbom (1979). MANOVA and SEM are compared on theoretical and practical grounds in Cole, Maxwell, Arvey, and Salas (1993). Note that the latest formulations of these models and associated software packages can now deal with nonnormal and categorical data.

When ordinal measures have been obtained, ANOVA on ranks of subjects" measures (with respect to the order in their respective group) rather than on absolute values may be applied instead of "genuine" ordinal methods as listed in Table 3. In the case of categorical measures, frequencies mostly have been obtained denoting the number of subjects with the characteristic feature of the category level in question present relative to the total number of subjects over the range of all possible levels of that categorical variable. Basically, analysis is carried out on an aggregate level (groups or subpopulations) rather than on the individual level, and link functions other than identity link are employed to regress independent variables (which have been of a categorical nature all the time: group membership, etc.) on to categorical outcome measures (now dependent variables have also become categorical). Regression coefficients must be interpreted differently, though, when dependent variables have been reconceptualized in this way. A positive β indicates that the probability of a specific category of a dependent variable is positively affected (risen) relative to another category, including the case of simply not being in that very category, when the characteristic feature of the category for an independent variable is present in a subject. In the case of a dichotomous dependent variable (logit models) interpretation is facilitated: β quantifies the effect of the independent variable on the odds, that is, the ratio of favorable to unfavorable responses (e.g., whether or not cancer is or will be present given the information available from independent variables). On a more formal level a nonzero regression coefficient in log-linear models indicates that the expected cell frequency in the category r of R categories or "levels" of the dependent variable departs from what would be expected in the "null" case of no effects, that is $n_r = n. = N/R$. As with the metric case, regression coefficients are considered effect parameters and tested for statistical significance by evaluating their standard error. Multiple group comparisons can be obtained in one of two ways: by introducing an independent variable denoting group membership, or by testing whether there is a significant change in the associated overall model fit indices from the more saturated model incorporating the effect in question (H_1) to the more restricted model dispensing with it (H_0).

3.04.7 CONCLUSION

In the last section are described the statistical models for multiple group comparisons. In most cases, however, analysis will be carried out using techniques presented in Table 3. It is reemphasized that it is not the complexity or elegance of the final data model that puts a good end to the process of quasi-experimental research: it is the fit of research questions or hypotheses and according methodological tools to tackle them. This is why a major part in this chapter is devoted to a presentation of an idealized procedural outline of this research process as sketched in Figure 1, and on discussing validity affairs. Generally speaking, the last step in this process lies with reversing it inductively and with introducing evaluative elements. It must be decided by which degree present patterns of statistical significance justify the induction that predictions derived from substantial hypotheses have instantiated as they should and whether validity issues have been attended to a degree that inference to the level of theory is admissible. Limitations in generalizability should be examined and problems encountered in the course of the study must be evaluated in order to point to future directions of research. With reference to Section 3.04.3.3, implications to clinical practice should be derived and be evaluated. In publications, these issues are usually covered in the "Results" and "Discussion" sections.

In the worked example study, the following discussion is offered:

> A result most relevant to clinical practice lies with the fact that cognitive and muscular relaxation both significantly reduce blood pressure and therapists may therefore choose from both methods with respect to their individual clients" special needs and aptitudes (differential indication). The critical prerequisite for this conclusion in terms of validity lies with clear separation of experimental instructions concerning either musculary or cognitively induced relaxation. It might be argued that any instruction relevant to improving irritating bodily sensations does feature cognitive elements, like expectancy, that contribute to intervention

effects. It might be better to differentiate between techniques involving direct muscular practice and a pool of techniques that dispense with the behavioral element. In the end, all relaxation techniques affect muscle tension. But persons might well vary on the degree to which they can benefit from direct or indirect techniques. It is known that more susceptible persons, or persons with greater ability to engage in and maintain vivid imagination and concentration, will benefit more from cognitive techniques, and that physical disabilities often rule out application of muscularly directed interventions. On the other hand, muscle relaxation instructions are considered easier to follow, and, after all, straight muscle relaxation techniques showed the greatest overall effect in the present study, thus pointing to a "safe-side" decision. These arguments refer to client selection in clinical practice as a parallel to the referred effects of subject selections in experimentation.

Accounting for the demand for both methodologically valid and practically relevant methods, the following guidelines for quasi-experimental research may be offered:

(i) preference for case–control designs,

(ii) preference for repeated measures designs, thus preference for diagnostic devices and statistical methods sensitive to (relative) change,

(iii) specification of hypotheses in terms of effect sizes,

(iv) consideration of multiple indicators per criterion, entailing a multivariate data setup, and

(v) special attention to balancing N (sample size), T (rep. measures level), ES (effect size), and other factors determining both statistical and practical significance of results presented in Section 3.04.3.1.

3.05.1 INTRODUCTION

3.05.1.1 Epidemiology and Clinical Psychology

Is psychological epidemiology an oxymoron? The primary goals of psychology differ from the primary goals of epidemiology. Psychology seeks to understand the general principles of psychological functioning of individual human beings. Epidemiology seeks to understand pathology in populations. These two differences—general principles vs. pathology, and individuals vs. populations—form the foundations for ideologic differences which have led to failures of linkage between the two disciplines, and many missed opportunities for scientific advances and human betterment. The gap between the two is widened by their location in different types of institutions: liberal arts universities vs. medical schools.

Various definitions of epidemiology reflect the notion of pathology in populations. Mausner and Kramer define epidemiology as "the study of the distribution and determinants of diseases and injuries in human populations" (1985, p. 1). Lilienfeld and Stolley use a very similar definition but include the notion that "epidemiologists are primarily interested in the occurrence of disease as categorized by time, place, and persons" (1994, p. 1). A less succinct, but nevertheless classic, statement is by Morris (1975), who listed seven "uses" of epidemiology:

(i) To study the hertory of health of populations, thus facilitating projections into the future.

(ii) To diagnose the health of the community, which facilitates prioritizing various health problems and identifying groups in special need.

(iii) To study the working of health services, with a view to their improvement.

(iv) To estimate individual risks, and chances of avoiding them, which can be communicated to individual patients.

(v) To identify syndromes, by describing the association of clinical phenomena in the population.

(vi) To complete the clinical picture of chronic diseases, especially in terms of natural hertory.

(vii) To search for causes of health and disease.

The seventh use is regarded by Morris as the most important, but, in reviewing the literature on psychiatric disorders for the third (1975) edition of his text, he was surprised at

> The sad dearth of hard fact on the causes of major as well as minor mental disorders, and so on how to prevent them ... [and] the dearth of epidemiological work in search of causes ... Lack of ideas? Methods? Money? It wants airing. Of course, the popular trend open-endedly to hand over to psychiatry (and to social work), in hope or resignation, the whole of the human condition is no help. (p. 220)

3.05.1.2 Dichotomy and Dimension

Pathology is a process, but diseases are regarded as present or absent. Psychologists have been interested historically in promoting health and in understanding the nature of each individual's phenomenology, leading to emphasis on dimensions of behavior; but epidemiologists have focused on disorders without much regard to individual differences within a given diagnostic category, leading to focus on dichotomies. For clinical psychologists adopting the epidemiologic perspective, the phrase "psychiatric epidemiology" could describe their work accurately (Tsuang, Tohen, & Zahner, (1995). Another area of work for psychologists in epidemiology focuses on psychological contributors to diseases in general, which can include psychiatric disorders but not be limited to them. This type of epidemiology might be termed "psychosocial epidemiology" (Anthony, Eaton, & Henderson, (1995), and receives less attention in this chapter.

Interest in normal functioning, or in deviations from it, has led psychologists to focus on statistical measures related to central tendency, such as the mean, and the statistical methods oriented toward that parameter, such as the comparison of means and analysis of variance. Epidemiology's base in medicine has led it to focus on the dichotomy of the presence or absence of disease. There is the old adage in epidemiology: "The world is divided into two types of persons: those who think in terms of dichotomies, and those who do not." The result for statistical analysis is recurring focus on forms involving dichotomies: rates and proportions (Fleiss, 1981), the two-by-two table (Bishop, Fienberg, & Holland, 1975), the life table (Lawless, 1982), and logistic regression (Kleinbaum, Kupper, & Morgenstern, 1982).

The epidemiologic approach is focused on populations. A population is a number of individuals having some characteristic in common, such as age, gender, occupation, nationality, and so forth. Population is a broader term than group, which has awareness of itself, or structured interactions: populations typically are studied by demographers, whereas groups typically are studied by sociologists. The general population is not limited to any particular class or characteristic, but includes all persons without regard to special features. In the context of epidemiologic research studies, the general population usually refers to the individuals who normally reside in the locality of the study. Many epidemiologic studies involve large populations, such as a nation, state, or a county of several hundred thousand inhabitants. In such large studies, the general population includes individuals with a wide range of social and biological characteristics, and this variation is helpful in generalizing the results. In the broadest sense, the general population refers to the human species. The fundamental parameters used in epidemiology often are conceptualized in terms of the population: for example, prevalence sometimes is used to estimate the population's need for health care; incidence estimates the force of morbidity in the population. Generally diseases have the characteristic of rarity in the population. As discussed below, rates of disease often are reported per 1000, 10 000, or 100 000 population.

Much of the logic that distinguishes the methods of epidemiology from those of psychology involves the epidemiologic focus on rare dichotomies. The case–control method maximizes efficiency in the face of this rarity by searching for and selecting cases of disease very intensively, for example, as in a hospital or a catchment area record system, and selecting controls at a fraction of their representation in the general population. Exposures can also be rare, and this possibility is involved in the logic of many cohort studies which search for and select exposed individuals very intensively, for example, as in an occupational setting with toxins present, and selecting nonexposed controls at a fraction of their representation in the general population. In both strategies the cases, exposed groups, and controls are selected with equal care, and in both strategies they are drawn, if possible, to represent the population at risk of disease onset: the efficiency comes in the comparison to a relatively manageable sample of controls.

3.05.1.3 Exemplar Study: Ecological Approach to Pellagra

The ecologic approach compares populations in geographic areas as to their rates of disease, and has been a part of epidemiology since its beginnings. A classic ecologic study in epidemiology is Goldberger's work on pellagra psychosis (Cooper & Morgan, 1973). The pellagra research also illustrates the concept of the causal chain and its implications for prevention. In the early part of the twentieth century, pellagra was most prevalent in the lower classes in rural villages in the southeastern US. As the situation may be in the 1990s for many mental disorders (Eaton & Muntaner, 1996), the relationship of pellagra prevalence to low social class was a consistent finding: a leading etiologic clue among many others with less consistent evidence. Many scientists felt that pellagra psychosis was infectious, and that lower class living situations promoted breeding of the infectious agent. But Goldberger noticed that there were striking failures of infection, for example, aides in large mental hospitals, where pellagra psychosis was prevalent, seemed immune. He also observed certain exceptions to the tendency of pellagra to congregate in the lower class, among upper-class individuals with unusual eating habits. Goldberger became convinced that the cause was a nutritional deficiency which was connected to low social class. His most powerful evidence was an ecologic comparison of high and low rate areas: two villages which differed as to the availability of agricultural produce. The comparison made a strong case for the nutritional theory using the ecological approach, even though he could not identify the nutrient. He went so far as to ingest bodily fluids of persons with pellagra to demonstrate that it was not infectious. Eventually a deficiency in vitamin B was identified as a necessary causal agent. Pellagra psychosis is now extremely rare in the US, in part because of standard supplementation of bread products with vitamin B.

Goldberger understood that low social class position increased risk of pellagra, and he also believed that nutritional deficiencies which resulted from lower class position were a necessary component in pellagra. With the advantage of hindsight, nutritional deficiency appears to have a stronger causal status, because there were many lower class persons who did not have pellagra, but few persons with pellagra who were not nutritionally deprived: vitamin B deprivation is a necessary cause, but lower social class position is a contributing cause. The concept of the causal chain points to both causes, and facilitates other judgements about the importance of the cause. For example, which cause produces the most cases of pellagra? (Since they operate in a single causal chain, the nutritional deficiency is more important from this point of view.) Which cause is antecedent in time? (Here the answer is lower social class position.) Which cause is easiest to change in order to prevent pellagra? The answer to this question is not so obvious, but, from the public health viewpoint, it is the strongest argument about which cause deserves attention. Which cause is consistent with an accepted framework of disease causation supportive of the ideology of a social group with power in society? Here the two causes diverge: funneling resources to the medical profession to cure pellagra is one approach to the problem consistent with the power arrangement in the social structure; another approach is redistributing income so that nutritional deficiency is less common. As it happens, neither approach would have been effective. The consensus to redistribute income, in effect, to diminish social class differences, is not easy to achieve in a democracy, since the majority are not affected by the disease. Bread supplementation for the entire population was a relatively cost-effective public health solution. The more general point is that Goldberger's work encompassed the complexity of the causal process.

Epidemiology accepts the medical framework as defining its dependent variable, but it is neutral as to discipline of etiology. Goldberger did not eliminate one or the other potential cause due to an orientation toward social vs. biological disciplines of study. He did not favor one or the other potential cause because it focused on the individual vs. the collective level of analysis. This eclecticism is an important strength in epidemiology because causes in different disciplines can interact, as they did in the case of pellagra, and epidemiology still provides a framework for study. The public health approach is to search for the most important causes, and to concentrate on those that are malleable, since they offer possibilities for prevention.

3.05.2 RATES

An early and well-known epidemiologist, Alexander Langmuir, used to say that "stripped to its basics, epidemiology is simply a process of obtaining the appropriate numerator and denominator, determining the rate, and interpreting that rate" (cited in Foege, 1996, p. S11). In the sense in which Langmuir was speaking, the term rates includes proportions such as the prevalence "rate" as well as the incidence rate, as explained below. Table 1 shows the minimum design requirements, and the definitions of numerators and denominators, for various types of the rates and proportions. The table is ordered from top to bottom by increasing difficulty of longitudinal follow-up.

3.05.2.1 Prevalence

Prevalence is the proportion of individuals ill in a population. Temporal criteria allow for several types of prevalence: point, lifetime, and period. Point prevalence is the proportion of individuals in a population at a given point in time. The most direct use of point prevalence is as an estimate of need for care or potential treatment load, and it is favored by health services researchers. It is also useful because it identifies groups at high risk of having a disorder, or greater chronicity of the disorder, or both. Finally, the point prevalence can be used to measure the impact of prevention programs in reducing the burden of disease on the community.

Lifetime prevalence is the proportion of individuals, who have ever been ill, alive on a given day in the population. As those who die are not included in the numerator or denominator of the proportion, the lifetime prevalence is sometimes called the proportion of survivors affected (PSA). It differs from the lifetime risk because the latter attempts to include the entire lifetime of a birth cohort, both past and future, and includes those deceased at the time of the survey. Lifetime risk is the quantity of most interest to geneticists. Lifetime prevalence also differs from the proportion of cohort affected (PCA), which includes members of a given cohort who have ever been ill by the study date, regardless of whether they are still alive at that time.

Lifetime prevalence has the advantage over lifetime risk and PCA in that it does not require ascertaining who is deceased, whether those deceased had the disorder of interest, or how likely those now alive without the disorder are to develop it before some given age. Thus, lifetime prevalence can be estimated from a cross-sectional survey. The other measures require either following a cohort over time or asking relatives to identify deceased family members and report symptoms suffered by them. Often these reports must be supplemented with medical records. The need for these other sources adds possible errors: relatives may forget to report persons who died many years before or may be uninformed about their psychiatric status; medical records may be impossible to locate or inaccurate; and the prediction of onset in young persons not yet affected requires the assumption that they will fall ill at the same rate as the older members of the sample and will die at the same ages if they do not fall ill. If risks of disorder or age-specific death rates change, these predictions will fail.

Lifetime prevalence requires that the diagnostic status of each respondent be assessed over his or her lifetime. Thus, accuracy of recall of symptoms after a possible long symptom-free period is a serious issue, since symptoms and disorders that are long past, mild, short-lived, and less stigmatizing are particularly likely to be forgotten. For example, data from several cross-sectional studies of depression seem to indicate a rise in the rate of depression in persons born after World War II (Cross-National Collaborative Group, 1992; Klerman & Weissman, 1989).

Table 1 Rates and proportions in epidemiology.

Rate	*Minimum design*	*Numerator*	*Denominator*
Lifetime prevalence	Cross-section	Ever ill	Alive
Point prevalence	Cross-section	Currently ill	Alive
Period prevalence (1)	Cross-section	Ill during period	Alive at survey
Period prevalence (2)	Two waves	Ill during period	Alive during period
First incidence	Two waves	Newly ill	Never been ill
Attack rate	Two waves	Newly ill	Not ill at baseline
Proportion of cohort affected	Birth to present	Ever ill	Born and still alive
Lifetime risk	Birth to death	Ever ill	Born

These persons are older, however, and it may be that they have forgotten episodes of depression which occurred many years prior to the interview (Simon & Von Korff, 1995). Data showing that lifetime prevalence of depressive disorder actually declines with age (Robins et al., 1984) is consistent with the recall explanation.

Period prevalence is the proportion of the population ill during a specified period of time. Customarily the numerator is estimated by adding the prevalent cases at the beginning of the defined period to the incident (first and recurrent) cases that develop between the beginning and the end of the period. This form is shown as period prevalence (2) in Table 1. In research based on records, all cases of a disorder found over a one-year period are counted. The denominator is the average population size during the interval. Thus, the customary definition of period prevalence requires at least two waves of data collection. Both Mausner and Kramer (1985) and Kleinbaum et al. (1982) have noted the advantages of period prevalence for the study of psychiatric disorders, where onset and termination of episodes is difficult to ascertain exactly (e.g., the failure to distinguish new from recurrent episodes is unimportant in the estimation of period prevalence). Furthermore, the number of episodes occurring during the follow-up is unimportant; it is important only to record whether there was one or more vs. none. The disadvantage of period prevalence is that it is not as useful in estimating need as point prevalence, nor as advantageous in studying etiology as incidence.

Another type of period prevalence, sometimes labeled by a prefix denoting the period, such as one-year prevalence, is a hybrid type of rate, conceptually mixing aspects of point and period prevalence, which has been found useful in the ECA Program (Eaton et al., 1985). This type of period prevalence is labeled period prevalence (1) in Table 1. It includes in the numerator all those surveyed individuals who have met the criteria for disorder in the past year, and as denominator all those interviewed. It is not a point prevalence rate because it covers a longer period of time, which can be defined as six months, two years, and so forth, as well as one year. But one-year prevalence is not a period prevalence rate because some individuals in the population who are ill at the beginning of the period are not successfully interviewed, because they either die or emigrate. As the time period covered in this rate becomes shorter, it approximates the point prevalence; as the time period becomes longer, the rate approaches the period prevalence. If there is large mortality, the one-year prevalence rate will diverge markedly from period prevalence.

3.05.2.2 Incidence

Incidence is the rate at which new cases develop in a population. It is a dynamic or time-dependent quantity and can be expressed as an instantaneous rate, although, usually, it is expressed with a unit of time attached, in the manner of an annual incidence rate. In order to avoid confusion, it is essential to distinguish first incidence from total incidence. The distinction itself commonly is assumed by epidemiologists but there does not appear to be consensus on the terminology. Most definitions of the incidence numerator include a concept such as "new cases" (Lilienfeld & Stolley, 1994, p. 109), or persons who "develop a disease" (Mausner & Kramer, 1985, p. 44). Morris (1975) defines incidence as equivalent to our "first incidence," and "attack rate" as equivalent to our "total incidence." First incidence corresponds to the most common use of the term "incidence," but since the usage is by no means universal, keeping the prefix is preferred.

The numerator of first incidence for a specified time period is composed of those individuals who have had an occurrence of the disorder for the first time in their lives and the denominator includes only persons who start the period with no prior history of the disorder. The numerator for attack rate (or total incidence) includes all individuals who have had an occurrence of the disorder during the time period under investigation, whether or not it is the initial episode of their lives or a recurrent episode. The denominator for total incidence includes all population members except those cases of the disorder which are active at the beginning of the follow-up period.

A baseline and follow-up generally are needed to estimate incidence. Cumulative incidence (not shown in Table 1) is the proportion of the sample or population who become a case for the first time between initial and followup interviews (Kleinbaum et al., 1982). But incidence generally is measured per unit of time, as a rate. When the follow-up period extends over many years, the exposure period of the entire population at risk is estimated by including all years prior to onset for a given individual in the denominator, and removing years from the denominator when an individual has onset or dies. In this manner, the incidence is expressed per unit time per population: for example, "three new cases per 1000 person years of exposure." This method of calculating facilitates comparison between studies with different lengths of follow-up and different mortality. When the mean interval between initial and follow-up interview is approximately 365 days, then the ratio of new cases to the number of followed up respondents, who were ascertained as being with a current or past history of the disorder at the time of the initial interview, can serve as a useful approximation of the disorder's annual first incidence.

First incidence also can be estimated by retrospection if the date of onset is obtained for each symptom or episode, so that the proportion or persons who first qualified in the year prior to the interview can be estimated. For this type of estimate (not shown in Table 1), only one wave of data collection is needed. This estimate of first incidence is subject to the effects of mortality, however, because those who have died will not be available for the interview.

The preference for first or total incidence in etiologic studies depends on hypotheses and assumptions about the way causes and outcomes important to the disease ebb and flow. If the disease is recurrent and the causal factors vary in strength over time, then it might be important to study risk factors not only for first but for subsequent episodes (total incidence): for example, the effects of changing levels of stress on the occurrence of episodes of neurosis (Tyrer, 1985) or schizophrenia (Brown, Birley, & Wing, 1972). For a disease with a presumed fixed progression from some starting point, such as dementia, the first occurrence might be the most important episode to focus on, and first incidence is the appropriate rate. In the field of psychiatric epidemiology, there are a range of disorders with both types of causal structures operating, which has led us to focus on this distinction in types of incidence.

The two types of incidence are related functionally to different measures of prevalence. Kramer et al. (1980) have shown that lifetime prevalence (i.e., the proportion of persons in a defined population who have ever had an attack of a disorder) is a function of first incidence and mortality in affected and unaffected populations. Point prevalence (i.e., the proportion of persons in a defined population on a given day who manifest the disorder) is linked to total incidence by the queuing formula $P = f(I \times D)$ (Kleinbaum et al., 1982; Kramer, 1957), that is, point prevalence is a function of the total number of cases occurring and their duration. In the search for risk factors that have etiologic significance for the disorder, comparisons based on point prevalence rates suffer the disadvantage that differences between groups as to the chronicity of the disorder: that is, the duration of episodes; the probability that episodes will recur; or the mortality associated with episodes; affect the comparisons (Kramer, (1957). For example, it appears that Blacks may have episodes of depression of longer duration than Whites (Eaton & Kessler, 1981). If so, the point prevalence of depression would be biased toward a higher rate for Blacks, based solely on their greater chronicity.

3.05.2.3 Incidence and Onset

Dating the onset of episodes is problematic for most mental disorders for many reasons. One is that the diagnostic criteria for the disorders themselves are not well agreed upon, and continual changes are being made in the definition of a case of disorder, such as the recent fourth revision of the *Diagnostic and statistical manual of mental disorders* (*DSM-III*; American Psychiatric Association, 1994). The *DSM-IV* has the advantage that criteria for mental disorders are more or less explicitly defined, but it is nevertheless true that specific mental disorders are often very difficult to distinguish from nonmorbid psychological states. Most disorders include symptoms that, taken by themselves, are part of everyone's normal experience: for example, feeling fearful, being short of breath or dizzy, and having sweaty palms are not uncommon experiences, but they are also symptoms of panic disorder. It is the clustering of symptoms, often with the requirement that they be brought together in one period of time or "spell," that generally forms the requirement for diagnosis. Although the clustering criteria are fairly explicit in the

DSM, it is not well established that they correspond to the characteristics generally associated with a disease, such as a predictable course, a response to treatment, an association with a biological aberration in the individual, or an associated disability. Thus, the lack of established validity of the criteria-based classification system exacerbates problems of dating the onset of disorder.

The absence of firm data on the validity of the classification system requires care about conceptualizing the process of disease onset. One criterion of onset used in the epidemiology of some diseases is entry into treatment, but this is unacceptable in psychiatry since people with mental disorders so often do not seek treatment for them. Another criterion of onset sometimes used is detectability, that is, when the symptoms first appear, but this is also unacceptable because experiences analogous to the symptoms of most psychiatric disorders are so widespread. It is preferable to conceptualize onset as a continuous line of development towards manifestation of a disease. There is a threshold at which the development becomes irreversible, so that at some minimal level of symptomatology it is certain that the full characteristics of the disease, however defined, will become apparent. This use of irreversibility is consistent with some epidemiological uses (Kleinbaum et al., 1982). Prior to this point, the symptoms are thought of as "subcriterial." At the state of knowledge in psychiatry in the 1990s, longitudinal studies in the general population, such as the ECA program and others mentioned above, are needed to determine those levels of symptomatology at which irreversibility is achieved.

There are at least two ways of thinking about development towards disease. The first way is the increase in severity or intensity of symptoms. An individual could have all the symptoms required for diagnosis but none of them be sufficiently intense or impairing. The underlying logic of such an assumption may well be the relatively high frequency of occurrence of the symptoms in milder form, making it difficult to distinguish normal and subcriterial complaints from manifestations of disease. For many chronic diseases, it may be inappropriate to regard the symptom as ever having been "absent," for example, personality traits giving rise to deviant behavior, categorized as personality disorders on Axis II of the *DSM* (APA, 1994). This type of development can be referred to as "symptom intensification," indicating that the symptoms are already present and have become more intense during a period of observation. This concept leads the researcher to consider whether there is a crucial level of severity of a given symptom or symptoms in which the rate of development towards a full-blown disease state is accelerated, or becomes irreversible.

A second way of thinking about progress towards disease is the occurrence of new symptoms which did not exist before. This involves the gradual acquisition of symptoms so that clusters are formed which increasingly approach the constellation required to meet specified definitions for diagnosis. A cluster of symptoms which occur more often together than would be expected by their individual prevalence in the population, that is, more often than expected by chance, is a syndrome. "Present" can be defined as occurrence either at a nonsevere or at a severe level, thus, decisions made about the symptom intensification process complicate the idea of acquisition. This idea leads the researcher to consider the order in which symptoms occur over the natural history of disease, and in particular, whether one symptom is more important than others in accelerating the process.

Figure 1 is an adaptation of a diagram used by Lilienfeld and Lilienfeld (1980, Figure 6.3) to visualize the concept of incidence as a time-oriented rate which expresses the force of morbidity in the population. In their original figure, (1(a)), the horizontal axis represents time and the presence of a line indicates disease. The adaptations (1(b) and 1(c)) give examples of the several distinct forms that onset can take when the disorder is defined by constellations of symptoms varying in intensity and co-occurrence, as is the case with mental disorders. In Figure 1(b), the topmost subject (1) is what might be considered the null hypothesis, and it corresponds to simple onset as portrayed in the original. Figure 1(b) shows how intensity, represented by the vertical width of the bars, might vary. The threshold of disease is set at four units of width, and in the null hypothesis subject 1 progresses from zero intensity to four units, becoming a case during the observation period. Subject 2 changes from nearly meeting the criteria (width of three units) to meeting it (four units) during the year. Both subjects 1 and 2 are new cases, even though the onset was more sudden in subject 1 than in subject 2, that is, the force of morbidity is stronger in subject 1 than subject 2. Subjects 3 and 4 are not new cases, even though their symptoms intensify during the year as much or more than those of subject 2.

Figure 1(c) adapts the same original diagram to conceptualize acquisition of symptoms and the development of syndromes. At one point in time there is no correlation between symptoms, but the correlation gradually develops, until there is a clear separation of the population into one group, with no association of symptoms,

and another group where the two symptoms co-occur. This example could be expanded to syndromes involving more than two symptoms.

Acquisition and intensification are indicators of the force of morbidity in the population, as are more traditional forms of incidence rate. But they are not tied to any one definition of caseness. Rather, these concepts allow study of disease progression independently of case definition. Risk factors at different stages of the disease may be differentially related to disease progression only above or below the threshold set by the diagnosis. In this situation, we might reconsider the diagnostic threshold.

3.05.3 MORBIDITY SURVEYS

Morbidity surveys are cross-sectional surveys of the general population. They are used to estimate prevalence of disease in the population as well as to estimate need for care. Morbidity surveys address Morris's (1975, discussed above) second "use" of epidemiology, "diagnosing the health of the community, prioritizing health problems and identifying groups in need;" as well as the third use "studying the working of health services;" and the fifth use, "identifying syndromes." Morbidity surveys are sometimes called the descriptive aspect of epidemiology, but they can also be used to generate hypotheses about associations in the population, and to generate control samples for cohort and case–control studies.

3.05.3.1 Exemplar Study: The Epidemiologic Catchment Area (ECA) Program

An example of a morbidity survey is the Epidemiologic Catchment Area (ECA) Program, sponsored by the United States National Institute of Mental Health from 1978 through 1985. The broad aims of the ECA Program were "to estimate the incidence and prevalence of mental disorders, to search for etiological clues, and to aid in the planning of health care facilities" (Eaton, Rogier, Locke, & Taube, 1981). The Program involved sample surveys of populations living in the catchment areas of already designated Community Mental Health Centers. The broad goals of the ECA Program are described in Eaton et al. (1981), the methods are described in Eaton and Kessler (1985), and Eaton et al. (1984), the cross-sectional results are described in Robins and Regier (1991), and the incidence estimates are described in Eaton, Kramer, Anthony, Chee, and Shapiro (1989).

A principal advantage of the morbidity survey is that it includes several or many disorders, which helps in assessing their relative importance from the public health point of view. Another advantage is that estimates of prevalence and association are measured without regard to the treatment status of the sample (Shapiro et al., 1984). Figure 2 displays results from the ECA study, showing the relatively high prevalence of phobia and relatively low prevalence of schizophrenia. The figure also shows the proportion meeting criteria for a given disorder within the last six months, who had seen either a physician or mental health specialist during that period. These proportions are well under 50%, with the exception of schizophrenia and panic disorder. For depression, which is disabling and highly treatable, less than a third of those with the disorder have received treatment.

3.05.3.2 Defining and Sampling the Population

Defining the target population for the morbidity survey is the first step. The best way to define the target population is not always clear, and different definitions have implications for the ultimate value of the results, as well as the feasibility of the study. A good definition of a target population is an entire nation, such as in the National Comorbidity Survey, or, better yet, a birth cohort of an entire nation, such as the British Perinatal Study, which included all births in Britain during a single week in March of 1958 (Butler & Alberman, 1969). Other studies usually involve compromises of one form or another. The goal of the sampling procedure is that each respondent is selected into the sample with a known, and nonzero,

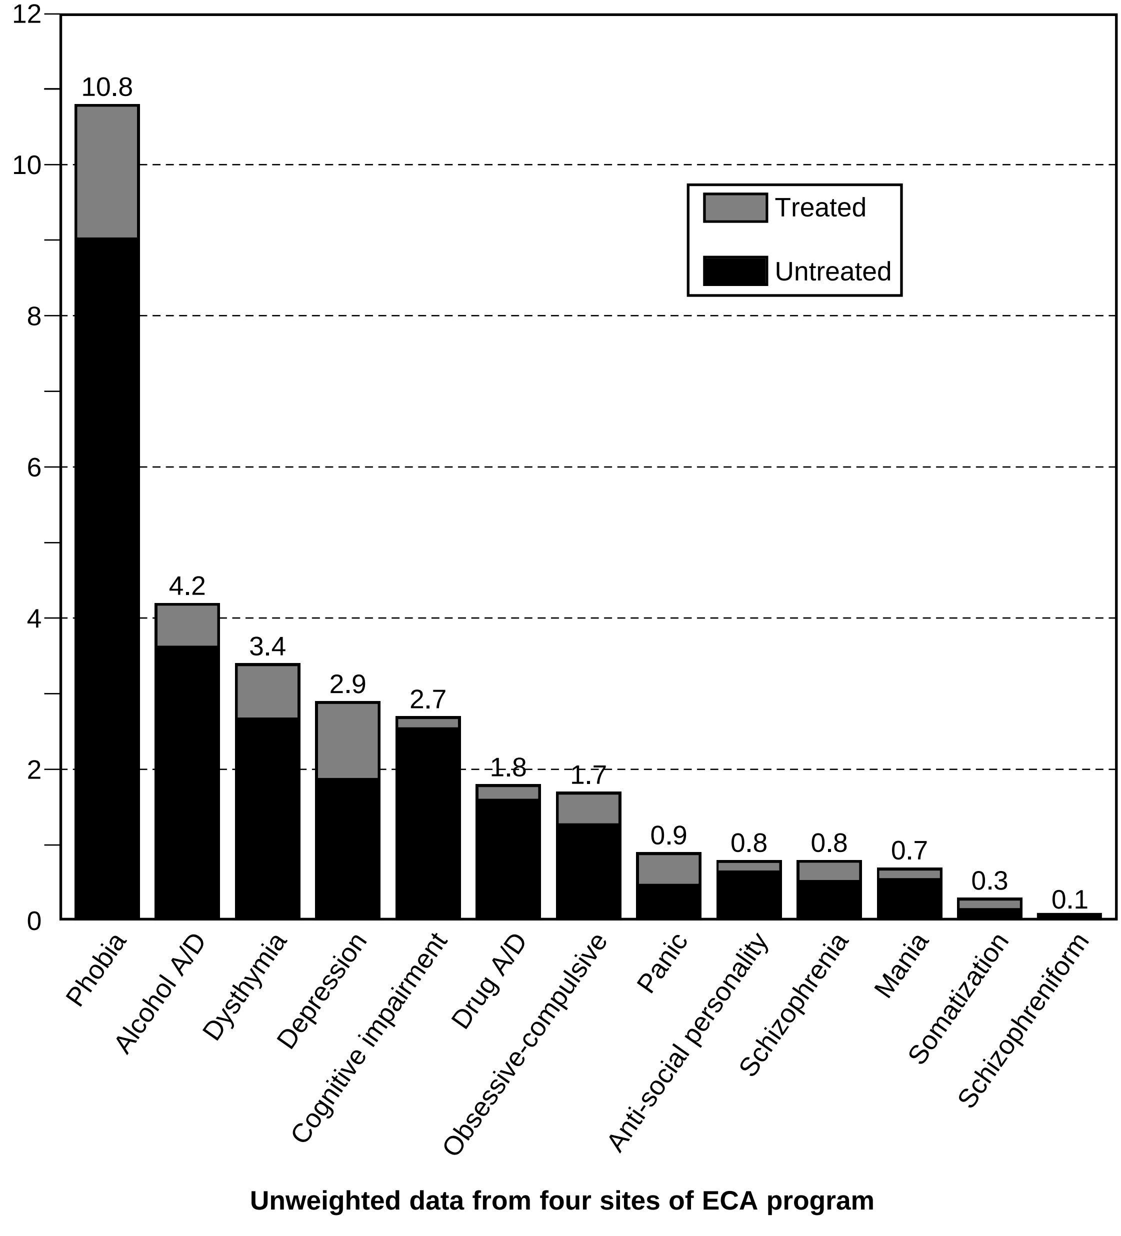

Figure 2 Prevalence of disorder in percent in six months prior to interview.

probability. Strict probabilistic sampling characterizes high-quality epidemiologic surveys, and is a requirement for generalization to the target population.

Most surveys are of the household residing, noninstitutionalized population, where the survey technology for sampling and interviewing individuals is strongest (e.g., Sudman, 1976). The ECA design defined the target population as "normal" residents of previously established catchment areas. Sampling was conducted in two strata, as shown in Figure 3. The household residing population was sampled via area probability methods or household listings provided by utility companies (e.g., as in Sudman, 1976). This stratum included short-stay group quarters such as jails, hospitals, and dormitories. After making a list of the residents in each household, the interviewer asked the person answering the door as to whether there were any other individuals who "normally" resided there but were temporarily absent. "Normally" was defined as the presence of a bed reserved for the individual at the time of the interview. Temporarily absent residents were added to the household roster before the single respondent was chosen randomly. If an individual was selected who was temporarily absent, the interviewer made an appointment for a time after their return, or conducted the interview at their temporary group quarters residence (i.e., in hospital, jail, dormitory, or other place). The ECA sampled the institutional populations separately, by listing all the institutions in the catchment area, as well as all those nearby institutions who admitted residents of the catchment area. Then the inhabitants of each institution were rostered and selected probabilistically. Sampling the institutional population required many more resources, per sampled individual, than the household sample, because each institution had to be approached individually. Inclusion of temporary and long-stay group quarters is important for health services research because many of the group quarters are involved in provision of health services, and because residents of group quarters may be high utilizers. The ultimate result of these procedures in the ECA was that each normal resident of the catchment area was sampled with a known probability.

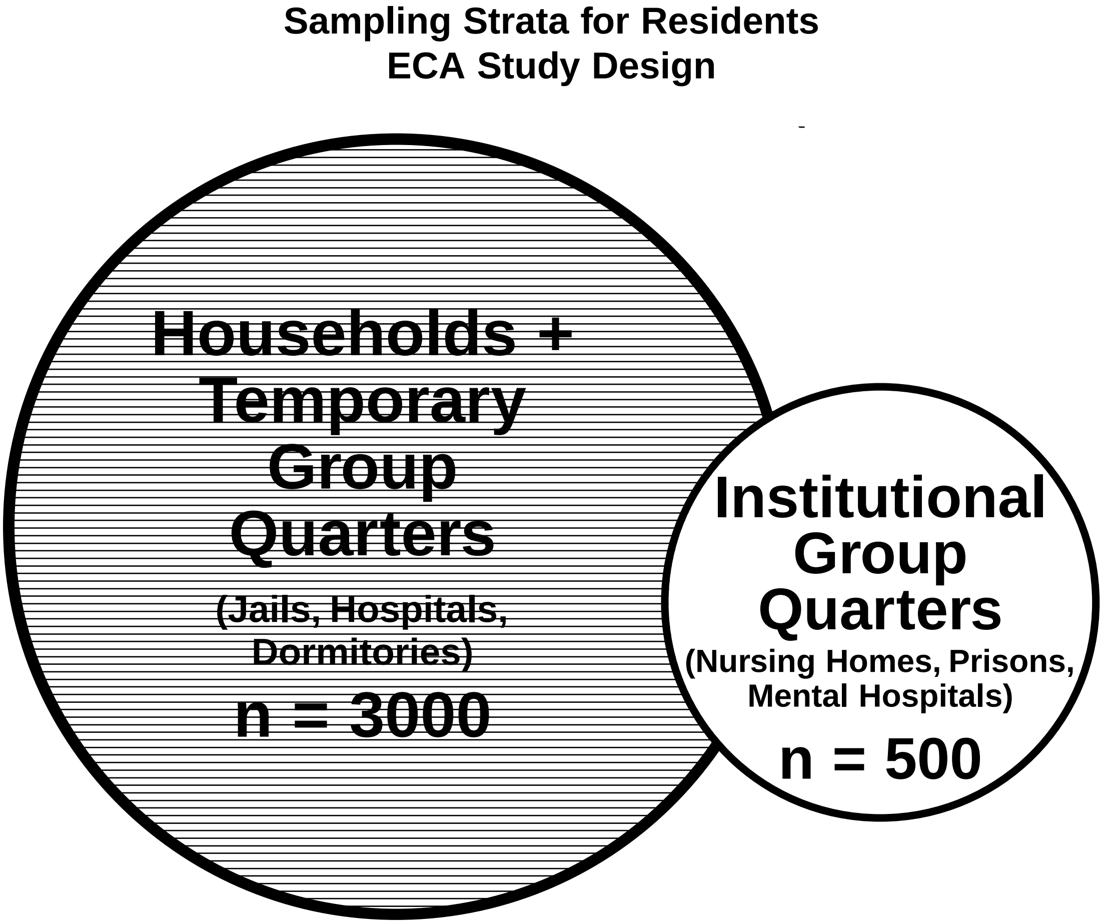
It is not enough to crisply define a geographic area, because different areas involve different limitations on the generalizability of results. A nationally representative sample, such as the National Comorbidity Survey (NCS; Kessler et al., 1994), may seem to be the best. But how are the results of the national sample to be applied to a given local area, where decisions about services are made? In the ECA the decision was made to select five separate sites of research in order to provide the possibility of replication of results across sites, and to better understand the effects of local variation (Eaton et al., 1981). The ECA target population thus consisted, not of the nation, but rather of an awkward aggregation of catchment areas. Nevertheless, the ECA data were considered as benchmarks for a generation of research (Eaton, 1994) because there was sufficient variation in important sociodemographic variables to allow generalization to other large populations, that is, sufficiently large subgroups of young and old, men and women, married and unmarried, rich and poor, and so forth. Generalization to other target populations, such as Asian-Americans or Native Americans, or to rural areas, was not logical from the ECA. But note that generalization from a national random sample to all rural areas, or to small ethnic groups, would likewise not always be possible. The point is that the target population should be chosen with a view toward later generalization.

3.05.3.3 Sample Size

General population surveys are not efficient designs for rare disorders or unusual patterns of service use. Even for research on outcomes that are not rare, sample sizes are often? larger than one thousand. A common statistic to be estimated is the prevalence, which is a proportion. For a proportion, the precision is affected by the square root of the sample size (Blalock, 1979). If the distribution of the proportion is favorable, say, 30–70%, then a sample size of 1000 produces precision which may be good enough for common sample surveys such as for voter preference. For example, a proportion of 0.50 has a 95% confidence interval from 0.47 to 0.53 with a sample of 1000. For rarer disorders, the confidence interval grows relative to the size of the proportion (i.e., 0.82–0.118 for a proportion of 0.10; 0.004–0.160 for a proportion of 0.01). Often, there is interest in patterns broken down by subpopulations, thus challenging the utility of samples with as few as 1000 individuals. Many community surveys, such as the ECA, have baseline samples in excess of 3000. It is important to estimate the precision of the sample for parameters of interest, and the power of the sample to test hypotheses of interest, before beginning the data collection.

3.05.3.4 Standardization of Data Collection

Assessment in epidemiology should ideally be undertaken with standardized measurement instruments which have known and acceptable



Sampling Strata for Residents

reliability and validity. In community surveys, and automated record systems, reliable and valid measurement must take place efficiently and in "field conditions." The amount of training for interviewers in household studies depends on the nature of the study. Interviewers in the Longitudinal Study on Aging (LSOA; Kovar, 1992), a well-known cohort study in the United States, received about 1.5 days of training (Fitti & Kovar, 1987), while ECA interviewers received slightly more than a week (Munson et al., 1985). Telephone interviews, such as in the LSOA, can be monitored systematically by recording or listening in on a random basis (as long as the subject is made aware of this possibility), but it is difficult to monitor household interviews, since it cannot be predicted exactly when and where the interview will take place.

The ECA Program involved a somewhat innovative interview called the Diagnostic Interview Schedule, or DIS (Robins, Helzer, Croughan, & Ratcliff, 1981). The DIS was designed to resemble a typical psychiatric interview, in which questions asked are highly dependent on answers already given. For example, if an individual responds positively to a question about the occurrence of panic attacks, a series of questions about that particular response are asked, but if the response to the question on panic is negative, the interviewer skips to the next section. In effect, the interview adapts to the responses of the subject, so that more questions are asked where more information is needed. The high degree of structure in the DIS required more than one week of training, as well as attention to the visual properties of the interview booklet itself. The result was that the interviewer could follow instructions regarding the flow of the interview, and the recording of data, smoothly, so as not to offend or alienate the respondent. Household survey questionnaires are becoming increasingly adaptive and response dependent, because more information can be provided in a shorter amount of time with adaptive interviews. Inexpensive laptop computers will facilitate such adaptive interviewing. Self-administered, computerized admission procedures are becoming more widely disseminated in the health care system, expanding the database, and facilitating the retrieval and linkage of records.

The reliability and validity of measurement are usually assessed prior to beginning a field study. Usually, the assessment involves pilot tests on samples of convenience to determine the optimal order of the questions, the time required for each section, and whether any questions are unclear or offensive. Debriefing subjects in these pilot tests is often helpful. The next step is a test of reliability and validity. Many pretests select samples from populations according to their health or services use characteristics in order to generate enough variation on responses to adequately estimate reliability and validity. In order to economize, such pretests are often conducted in clinical settings. But such pretests do not predict reliability and validity under the "field" conditions of household interviews. The ECA Program design involved reliability and validity assessment in a hospital setting (Robins et al., 1981), and later under field conditions (Anthony et al., 1985). The reliability and validity of the DIS were lower in the household setting.

3.05.4 EXPOSURE AND DISEASE

Two basic research designs in epidemiology are the cohort and the case–control design. These designs are used mostly in addressing Morris' seventh "use" of epidemiology, the search for causes. This is sometimes called the analytic aspect of epidemiology. These designs differ in their temporal orientation to collection of data (prospective vs. retrospective), and in the criteria by which they sample (by exposure or by caseness), as shown in Table 2.

3.05.4.1 Cohort Design

In a cohort design, incidence of disorder is compared in two or more groups which differ in some exposure thought to be related to the disorder (Table 2). The cohort design differs from the morbidity survey in that it is prospective, involving longitudinal follow-up of an identified cohort of individuals. As well as the search for causes, the cohort design addresses Morris' fourth "use" of epidemiology, "estimating individual risks;" and the sixth "use," that is, "completing the clinical picture, especially the natural history." The entire cohort can be sampled, but when a specific exposure is hypothesized, the design can be made more efficient by sampling for intensive measurement on the basis of the putative exposure, for example, children living in an area of toxic exposures, or with parents who have been convicted of abuse, or who have had problems during delivery, and a control group from the general population. Follow-up allows comparison of incidence rates in both groups.

3.05.4.2 Exemplar Study: the British Perinatal Study

An example is the British Perinatal Study, a cohort study of 98% of all births in Great Britain during a single week in March, 1958 (Butler & Alberman, 1969; Done, Johnstone, & Frith, 1991; Sacker, Done, Crow, & Golding, 1995). The cohort had assessments at the ages of 7 and 11 years, and, later, mental hospital records were linked for those entering psychiatric hospitals between 1974 and 1986, by which time the cohort was 30 years old. Diagnoses were made from hospital case notes using a standard system. There was some incompleteness in the data, but not too large, for example, 12 of the 49 individuals diagnosed as "narrow" schizophrenia were excluded because they were immigrants, multiple births, or because they lacked data. It is difficult to say how many individuals in the cohort had episodes of disorder that did not result in hospitalization, but that does not necessarily threaten the results, if the attrition occurred equally for

Table 2 Case–control and cohort studies.

		Case–control study		
		Cases	Controls	
Cohort	Exposed	a	b	$a + b$
Study	Not exposed	c	d	$c + d$

$$\text{Relative risk} = \frac{a/(a+b)}{c/(c+d)}$$

$$\text{Relative odds} = \frac{a/b}{c/d} = \frac{ad}{bc}$$

different categories of exposure. Table 3 shows results for one of 37 different variables related to birth, that is, "exposures," that were available in the midwives' report: birth weight under 2500 g. With n given at the head of the columns in Table 3, the reader can fill in the four cells of a two-by-two table, as in Table 2, for each of the four disorders. For example, the cells, labeled as in Table 2, for narrow schizophrenia, are: a–5; b–706; c–30; d–16 106. The number with the disorder is divided by the number of births to generate the risk of developing the disorder by the time of follow-up: the cumulative incidence. The risks can be compared across those with and without the exposure. In Table 2, the incidence of those with exposure is $a/(a+b)$, and the incidence of those without exposure is $c/(c+d)$. The relative risk is a comparison of the two risks: $[a/(a+b)]/[c/(c+d)]$. For narrow schizophrenia the relative risk is (RR = [5/711]/[30/16 136]), or 3.78.

The relative risk is closely related to causality since it quantifies the association in the context of a prospective study, so the temporal ordering is clear. The relative risk is approximated closely by the relative odds or odds ratio, which does not include the cases in the denominator (i.e., OR = [5/706]/[30/16 106] = 3.80, not 3.78). The odds ratio has many statistical advantages for epidemiology. It is easy to calculate in the two-by-two table by the cross-products ratio (i.e., ad/bc). The odds ratio quantifies the association without being affected by the prevalence of the disorder or the exposure, which is important for the logic of cohort and case–control studies, where these prevalences may change from study to study, depending on the research design. This lack of dependence on the marginal distribution is not characteristic of many measures of association typically used in psychology, such as the correlation coefficient, the difference in proportions, or the kappa coefficient (Bishop et al., 1975). The odds ratio is a standard result of logistic regression, and can be adjusted by other factors such as gender, age, and so forth. The odds ratio for low birth weight and narrow schizophrenia in the British Perinatal Study, as it happens, was 3.9, after adjustment for social class and other demographic variables.

The logic of the cohort study includes assessing the natural history of the disorder, that is, the study of onset and chronicity, in a population context without specific intervention by the researcher. Study of natural history requires repeated follow-up observations. In the British Perinatal Study, there were assessments of the cohort at the ages of 7 and 11. Once the case groups had been defined, it was possible to study their reading and mathematics performance well before hospitalization. Those destined to become schizophrenic had lower reading and mathematics scores at both 7 and 11 years of age (Crow, Done, & Sacker, 1996). Males who would eventually be diagnosed schizophrenic had problems relating to conduct during childhood, while females were anxious, as compared to children who did not end up being hospitalized with a diagnosis of schizophrenia later. Later follow-ups in this study may economize by studying only those who have had onset, and a small random subsample of others, to estimate such factors as the length of episodes, the probability of recurrences, prognostic predictors, and long-term functioning.

3.05.4.3 Case–Control Design

In the case–control study, it is the disease or disorder which drives the logic of the design, and many factors can be studied efficiently as possible causes of the single disorder (Schlesselman, 1982). The case–control study may be the most important contribution of epidemiology to the advancement of public health, because it is so efficient in searching for causes when there is little knowledge. For example, adenocarcinoma of the vagina occurs so rarely, that, prior to 1966, not a single case under the age of 50 years

Table 3 Mental disorder and low birth weight: British Perinatal study.

	Cumulative incidence per 1000		
Disorder	*Low birth weight (n = 727)*	*Normal birth weight (n = 16 812)*	*Odds ratio*
Narrow schizophrenia (n = 35)	7.03	1.86	3.8
Broad schizophrenia (n = 57)	9.82	3.09	3.2
Affective psychosis (n = 32)	8.43	1.61	5.3
Neurosis (n = 76)	4.23	4.51	0.9

Source: Adapted from Sacker et al. (1995).

had been recorded at the Vincent Memorial Hospital in Boston. A time-space clustering of eight cases, all among young women born within the period 1946–1951, was studied (Herbst, Utfeder, & Poskanzer, 1971). There was almost no knowledge of etiology. A case–control study was conducted, matching four controls to each case. The study reported a highly significant ($p < 0.00001$) association between treatment of the mothers with estrogen diethylstilbestrol during pregnancy and the subsequent development of adenocarninoma of the vagina in the daughters. The results led to recommendations to avoid administering stilbestrol during pregnancy. Logistic regression, developed by epidemiologists and used in case–control studies, has distinct advantages over analysis of variance, ordinary least-squares regression, discriminant function analysis, and probit regression, developed by agronomists, psychologists, economists, and educational psychologists, especially when the dichotomous dependent variable has a very skew distribution, that is, is very rare.

3.05.4.4 Exemplar Study: Depression in Women in London

The most convincing demonstration of social factors in the etiology of any mental disorder is *The social origins of depression*, by Brown and Harris (1978). That study used the case–control method to demonstrate the importance of life-event stresses and chronic difficulties as causal agents provoking the onset of depression. The method involved indepth diagnostic and etiologic interviews with a sample of 114 patients and a sample of 458 household residents. The target population is that residing in the Camberwell area in south London.

The analysis presented by Brown and Harris is logical but does not always follow the standard epidemiologic style. Table 4 presents the crucial findings in the typical epidemiologic manner (following Table 2). Two case groups are defined: the 114 women presenting at clinics and hospitals serving the Camberwell area, diagnosed by psychiatrists using a standardized clinical assessment tool called the Present Examination, and 76 women in the community survey (17%) who were depressed at the time of the survey, as judged by a highly trained, nonmedical interviewer using a shortened version of the same instrument. Sixty-one percent of the patient cases (70/114) and 68% of the survey cases (52/76) experienced the "provoking agent" of a severe life event during the year prior to the onset of depression. Twenty percent (76/382) of the healthy controls experienced such an event in the year prior to the interview. Patient cases had 6.4 times the odds of having experienced a life event than the controls (i.e., [70/44]/[76/306]).

The case–control study is very efficient, especially when the disease is rare, because it approximates the statistical power of a huge cohort study with a relatively limited number of controls. For a disease like schizophrenia, which occurs in less than 1% of the population, 100 cases from hospitals or a psychiatric case register can be matched to 300 controls from the catchment area of the hospital. A cohort study of this number would involve measurements on 10 000 persons instead of 400! Since the disease is rare, it may be unnecessary to conduct diagnostic examinations on the group of controls, which would have only a small number of cases. Furthermore, a few cases distributed among the controls would weaken the comparison of cases to controls, generating a conservative bias. The statistical power of the case–control study is very close to that of the analogous cohort study, and, as shown above, the odds ratio is a close estimate of the relative risk. The case–control study can be used to test hypotheses about exposures, but it has the very great ability to make comparisons across a wide range of possible risk factors, and can be useful even when there are very few hypotheses available.

3.05.5 USING AVAILABLE RECORDS

3.05.5.1 Government Surveys

There are many sources of data for psychiatric epidemiologic research which are available to the public. These include statistics from

Table 4 Depression and life events and difficulties in London.

	Cases (patients)		*Cases (survey)*		*Controls (survey)*	
One or more severe event	70	61%	52	68%	76	20%
No severe events	44	39%	24	32%	306	80%
	114	100%	76	100%	382	100%

Source: Brown & Harris (1978).

treatment facilities and from large sample surveys of the populations conducted by a large organization such as national governments. Often the measures of interest to psychologists are only a small part of the survey, but the availability of a range of measures, drawn from other disciplines, can be a strong advantage. In the United States an important source of data is the National Center for Health Statistics (NCHS). For example, the Health and Nutrition Examination Survey (HANES) is a national sample survey conducted by the NCHS involving physical examinations of a sample of the United States population. Its first phase included the Center for Epidemiologic Studies Depression Scale as part of its battery of measures, which included anthropometric measures, nutritional assessments, blood chemistry, medical history, and medical examinations (Eaton & Kessler, 1981; Eaton & McLeod, (1984).

Later phases of the HANES included portions of the DIS. The Health Interview Survey conducts health interviews of the general population of the United States, and includes reports by the respondent of named psychiatric disorders such as schizophrenia, depressive disorder, and so forth. The National Medical Care Utilization and Expenditure Survey (MCUES) is conducted by the NCHS to help understand the health service system and its financing. The MCUES samples records of practitioners from across the nation, and there are several questions on treatment for psychological problems.

Some governments also sponsor national surveys which focus on psychological disorders. The ECA is one such example, although it was not, strictly speaking, a sample of the nation. The later National Comorbidity Survey includes 8058 respondents from a probability sample of the US, with its major measurement instrument being a version of the Composite International Diagnostic Interview (CIDI), a descendant of the DIS used in the ECA surveys (Kessler et al., 1994). The British government conducted a large survey of psychological disorders in a national sample, using a similar instrument to the DIS and CIDI (Meltzer, Gill, Pettirew, & Hindi, 1995a, 1995b). Anonymous, individual level data from the ECA, the British survey, and the NCS are available at nominal cost.

3.05.5.2 Vital Statistics

Governments generally assimilate data on births, deaths, and marriages from states, provinces, or localities, ensuring some minimal degree of uniformity of reporting and creating data files for public use. The mortality files usually list the cause of death, including suicide. These data files are often available from the government at nominal cost.

3.05.5.3 Record-based Statistics and Record Linkage

Statistics originating from treatment facilities can also be put to good use in psychiatric epidemiology. Many early epidemiologic studies used hospital statistics as the numerators in estimating rates, and census statistics in the denominators (Kramer, 1969). The utility of rates estimated in this manner is dependent on the degree to which the clinical disorder is associated with treatment, a stronger association for severe schizophrenia than for mild phobia, presumably. The value of these rates also depends on the relative scarcity or abundance of treatment facilities. In the United States, Medicaid and Medicare files, which include such data as diagnosis and treatment, are available for research use. Many Health Maintenance Organizations maintain data files which could be used in psychological epidemiological research.

Statistics from treatment facilities are enhanced considerably by linkage with other facilities in the same geographic area, serving the same population (Mortensen, 1995). Although the number has declined, there still exist several registers which attempt to record and link together all psychiatric treatment episodes for a given population (ten Horn, Giel, Gulbinar, & Henderson, 1986). Linkage across facilities allows multiple treatment episodes for the same individual (even the same episode of illness) to be combined into one record (so-called "unduplicating"). Linkage across time allows longitudinal study of the course of treatment. Linkage with general health facilities, and with birth and mortality records, provides special opportunities. The best known example of a comprehensive health registry is the Oxford Record Linkage Study (ORLS; Acheson, Baldwin, & Graham, 1987), which links together all hospital treatment episodes in its catchment area. The database of the ORLS consists of births, deaths, and hospital admissions, which is a strong limitation. However, due to the catchmenting aspect of the British National Health Service, the data are not limited to the household-residing population, as is the National Comorbidity Survey, for example, or the LSOA. In automated data collection systems such as the ORLS, the recordation is often done under the auspices of the medical record systems, with data recorded by the physician, such as the diagnosis. It cannot be presumed that physician's diagnosis is "standardized" and therefore more reliable than other interview or record data. In fact, there is significant variation in diagnosis among physicians. Research using measurements and diagnoses recorded by the physician, as in record linkage systems such as the ORLS, should ideally include studies of reliability and validity (e.g., Loffler et al., 1994).

3.05.5.4 Exemplar Study: the Danish Adoption Study

An example of the benefits of record linkage in psychological research is the adoption study of schizophrenia in Denmark (Kety, Rosenthal, Wender, Schulsinger, & Jacobsen, 1975). Familial and twin studies of schizophrenia suggested strongly that schizophrenia was inherited, but these studies were open to the interpretation that the inheritance was cultural, not genetic, because family members are raised together, and identical twins may be raised in social environments which are more similar than the environments of fraternal twins. The Danish Adoption Study ingeniously combined the strategy of file linkage with interviews of cases, controls, and their relatives. In Denmark, each individual receives a number at birth which is included in most registration systems. The registration systems are potentially linkable, after appropriate safeguards and clearances. In the adoption study, three registers were used. First, all 5483 individuals in the county and city of Copenhagen who had been adopted by persons or families other than their biological relatives, from 1924 through 1947, were identified from a register of adoptions (Figure 4). These were linked to the psychiatric case register, wherein it was determined that 507 adoptees had ever been admitted to a psychiatric hospital. From case notes in the hospitals, 34 adoptees who met criteria for schizophrenia (about 0.5% of of the total number of adoptees) were selected, and matched on the basis of age, sex, socioeconomic status of the adopting family, and time with biologic family, or in institution, prior to adoption. The relatives of these 68 cases and controls were identified by linkage with yet another register in Denmark which permits locating families, parents, and children. After allowing for mortality, refusal, and a total of three who were impossible to trace, a psychiatric interview was conducted on 341 individuals (including 12 on whom the interview was not conducted but sufficient information for diagnosis was obtained). Eleven of the 118 biologic relatives of the index adoptees were schizophrenic (9%), vs. one in the 35 relatives of adoptive families of the index adoptees (3%), and three of the 140 biologic relatives of the control adoptees (2%). The findings for schizophrenia spectrum disorders (including uncertain schizophrenia and schizoid personality) also show a pattern consistent only with genetic inheritance (26/118 in the biologic relatives of index cases, or 22%, vs. 16/140 biologic relatives of control adoptees, or 14%).

3.05.6 PREVENTIVE TRIALS

3.05.6.1 The Logic of Prevention

Some of the earliest epidemiologists used interventions in the community to stop an epidemic or to gather information about the causes of diseases in the population. This is sometimes called the experimental aspect of epidemiology. The best known experiment is that conducted by Snow in the cholera epidemic in London. Snow's work exemplifies epidemiologic principles in several ways (Cooper & Morgan, 1973). It was widely believed that cholera was spread through the air, in a miasma, leading many to seek safety by retreating to rural areas. Snow showed with ecologic data in London that areas serviced by a water company taking water from upstream in the Thames had lower rates of cholera than areas serviced by a company taking water from downstream. This ecologic comparison suggested that cholera was borne by water. In the context of a single cholera epidemic, Snow identified individual cases of cholera, showing that they tended to cluster around a single water pump at Broad Street. He further showed that many exceptional cases, that is, cases of cholera residing distant from the pump, had actually drawn or drank water from that pump (e.g., on their way home from work). His action to remove the handle of the pump, which roughly coincided with the termination of the epidemic, is regarded as an early instance of experimental epidemiology.

In epidemiology, as with medicine generally, intervention is valued if it is effective, regardless of whether the causation of the disease is understood or not. Table 5 shows examples of preventive measures which were implemented well prior to knowledge of the cause, discovered much later in many cases. This logic leads to experimentation even in the absence of causal information.

Various conceptual frameworks have been used to organize the area of prevention research. The Commission on Chronic Illness (1957) divided prevention into three types, dependent on the stage of the disease the intervention was designed to prevent or treat. Prior to onset of the disease, the prevention was primary, and its goal was to reduce incidence; after disease onset, the intervention was directed at promoting

recovery, and its goal was to reduce prevalence, so-called secondary prevention. Tertiary prevention was designed to prevent impairment and handicap which might result from the disease. The Institute of Medicine (Mrazek & Haggerty, 1994) integrated this framework into that of Gordon (1983), who directed attention at the population to which the preventive intervention was directed: universal preventions at the entire general population; targeted interventions at subgroups at high risk of development of disorder; and indicated interventions, directed at individuals who have already manifest signs and symptoms of the disease. The results of integrating the two frameworks are shown in Figure 5. Curative medicine generally operates in the area of secondary prevention, with indicated interventions. Rehabilitative medicine is in the area of tertiary prevention. Primary, universal, and targeted interventions are the province of experimental epidemiology. Prominent examples of universal interventions in the area of epidemiology are various smoking cessation campaigns, and such studies as the Stanford Five-City Project, which was designed to reduce risk of heart disease by lowering levels of several associated risk factors (Farquhar et al., 1990).

3.05.6.2 Attributable Risk

From among many possibilities, how should interventions be selected? Epidemiology provides a helpful tool in the form of the Population Attributable Risk, sometimes called the Attributable Fraction or the Etiologic Fraction (Lilienfeld & Stolley, 1994, p. 202). The attributable risk is the maximum estimate of the proportion of the incidence of disease that would be prevented if a given risk factor were eliminated. For a given disease, the attributable risk combines information from the relative risk for a given exposure with the prevalence of the exposure in the population. The formula for attributable risk is:

$$\text{Attributable Risk} = \frac{\text{P(RR} - 1)}{\text{P(RR} - 1) + 1}$$

where:
P = Prevalence of Exposure, and
RR = Relative Risk of Exposure to Disease

The relative risk can be estimated from a cohort study, as described above, and the prevalence of the exposure can be estimated from a separate survey. A simple case–control study also provides the information for attributable risk, under certain conditions. The relative risk is approximated by the relative odds, as discussed above. If the controls are selected from the general population, the level of exposure can be estimated from them. For example, case–control studies of smoking and lung cancer in the early 1950s showed that the odds of dying from lung cancer were about 15 times higher for smokers as for nonsmokers. About half the population smoked, leading to the attributable risk estimate of about 80%. In the United States, this meant that about 350 000 of the 400 000 annual deaths due to lung cancer would not occur if smoking were eliminated totally. In the situation of many possible risk factors, the attributable risk is a tool which helps prioritize them.

Epidemiologic cohort studies can provide information which may help to stage the intervention at the most appropriate time. The intervention should occur before most onsets in the population have taken place, but not so far before onset that the effects of the intervention wash out before the process of disease development has begun. The appropriate stage for prevention in many situations would appear to be that of precursors, in which there are subgroups which can be identified at high risk, but before the disease prodrome has started (Eaton et al., 1995).

3.05.6.3 Developmental Epidemiology

Epidemiologists are gradually becoming aware of the need for life course perspective (Kellam & Werthamer-Larson, 1986). In social and psychological research on human beings, cohort studies may suggest regularities in human development which can be considered etiologic clues. The clues consist of temporal sequences of various behaviors over several years, with only a probabilistic connection between each behavior. The behaviors may have a common antecedent, such as a genetic background, or they may depend on the sequence of environments that the individual experiences, and the interaction between environments, genetic traits, and habits formed by the history of prior behaviors. The epidemiologic notion of exposures, developed in the context of infectious agents and toxins, is too simple to be useful in these multicausal, developmental sequences. For example, aggressive behavior by boys in early elementary school years is followed by conduct problems in middle

school; later behaviors such as smoking cigarettes, having sexual relations at an early age, and drinking alcohol, in high school, and, eventually, the diagnosis of antisocial personality disorder as an adult. Which of these are essential causes, and which simply are associated behaviors which have no influence on the causal chain to the outcome (in this example, the diagnosis of antisocial personality disorder)? Since the chain of causes is probabilistic and multicausal, the notion of attributable risk (discussed above) is too simplistic, and it is unlikely that any estimate of attributable risk would be even moderate in size. A preventive intervention trial with random or near-random assignment to conditions which manipulate a putative cause may be the only way to generate an understanding of the causal chain. The preventive trial serves the traditional purpose in epidemiology of testing the efficacy of the intervention, but it also serves as an examination of the developmental pathway leading to disorder, for building and testing theories.

3.05.6.4 Exemplar Study: the Johns Hopkins Prevention Trial

An example of a preventive intervention trial is the Johns Hopkins Prevention Trial (Kellam, Rebek, Ialongo, & Mayer, 1994). The trial was designed to examine developmental pathways generally occurring after two important characteristics which could be identified in first graders: success at learning (especially, learning to read) and aggressive behavior. Table 6 shows the design of the trials, using the notation of experimental and quasi-experimental design in psychology (Campbell & Stanley, 1971). The population for the trial was carefully defined in epidemiologic terms to include all first graders in public schools in an area of Baltimore. The Baltimore City Public School system was an active participant in the research. The 19 schools were divided into five levels, with three or four schools per level, based on the socioeconomic characteristics of the areas they served. At each of the five levels there was a control school and two experimental schools. For the study of aggressive behavior, 153 children were assigned at random to eight separate classrooms in which the teacher used a special classroom procedure called the "Good Behavior Game," which had been shown to reduce the level of aggressive behavior in classrooms. Nine classrooms with 163 children received an intervention to improve reading mastery, and there were 377 children who were in control classrooms. The control classrooms consisted of classrooms in the same school as the experimental, but who did not receive the intervention; and classrooms in schools in the same area of Baltimore, where there were no interventions at all. One outcome of the Good Behavior Game Trial was that the median level of aggressive behavior went down during the period of the trial for those in the experimental group. For controls, the level of aggressive behavior was relatively stable. The most impressive result was that aggressive behavior continued to decline in the experimental group, even after discontinuation of the intervention in third grade, at least through the spring of sixth grade.

3.05.7 BIAS

Epidemiologic research entails bias, and it is beneficial to anticipate bias in designing research studies. Common biases in epidemiology take a slightly different form than in typical psychological research (e.g., as enumerated in Campbell & Stanley, 1971), but the principle of developing a language to conceptualize bias, and to attempts to anticipate, eliminate, or measure bias is common to both disciplines. In this section five basic types of bias are considered: sampling bias, divided into three subtypes of treatment bias, prevalence bias, and response bias; and measurement bias, divided into subtypes of diagnostic bias and exposure bias.

3.05.7.1 Sampling Bias

Sampling bias arises when the sample studied does not represent the population to which generalization is to be made. An important type of sampling bias is treatment bias. The case–control design often takes advantage of treatment facilities for finding cases of disorder to compare with controls. With severe diseases which invariably lead to treatment, there is less bias than for disorders which are less noticeable, distressing, or impairing to the individual. As shown in Figure 2, data from the ECA Program indicate that among the mental disorders, only for schizophrenia and panic disorder are as many as half the current cases under treatment. In 1946, Berkson showed that, where the probability of treatment for a given disorder is less than 1.0, cases in treatment overrepresented individuals with more than one disorder, that in, comorbid cases. In studying risk factors for disorder with the case–control design, where cases are found through clinics, the association revealed in the data may be an artifact of the comorbidity, that is, exposure x may appear to be associated with disease y, the focus disorder of the study, but actually related to disease z (perhaps not measured in the study). This type of bias is so important in epidemiologic research, especially case–control studies, it is termed “Berkson's bias,” or sometimes “treatment bias.” The existence of this bias is possibly one factor connected to little use of the case–control design in studies of psychiatric disorders.

Another type of sampling bias very common in case–control studies arises from another type of efficiency in finding cases of disorder, that in, the use of prevalent cases. This is sometimes termed prevalence bias, or the clinician's illusion (Cohen & Cohen, 1984). The ideal is to compare relative risks among exposed and nonexposed populations, which entails comparison of incidence rates, as discussed above. But the rate of incidence is often too low to generate sufficient cases for analysis, and necessitates extending the data collection over a period of months or years during which new cases are collected. Prevalent cases are easier to locate, either through a cross-sectional survey, or, easier yet, through records of individuals currently under treatment. The problem with study of current cases is that the prevalence is a function of the incidence and chronicity of the disorder, as discussed above. Association of an exposure with the presence or absence of disease mixes up influences on incidence with influences on chronicity. Influences on chronicity can include treatment. For example, comparing the brain structure of prevalent cases of schizophrenia to controls showed differences in the size of the ventricles, possibly an exciting clue to the etiology of schizophrenia. But a possible bias is that phenothiazine or other medication, used to treat schizophrenia, produced the changes in brain structure. Later studies of brain structure had to focus on schizophrenics who had not been treated in order to eliminate this possibility. The study of depression among women in London is possibly subject to prevalence bias since cases were selected on the basis of presentation to treatment, and controls via a cross-sectional (prevalence) survey. Thus, it may be that provoking agents such as life events contribute only to the recurrence of episodes of depression, not necessarily to their initial onset.

Response bias is a third general threat to the validity of findings from epidemiologic research. The epidemiologic design includes explicit statements of the population to which generalization is sought, as discussed above. The sampling procedure includes ways to designate individuals thought to be representative of that population. After designation as respondents, before measurements can be taken, some respondents become unavailable to the research, usually through one of three mechanisms: death, refusal, or change of residence. If these designated-but-not-included respondents are not a random sample, there will be bias in the results. The bias can result from differences in the distribution of cases vs. noncases as to response rate, or to differences in distribution of exposures, or both. In cross-sectional field surveys (Von Korff et al., 1985) and in follow-up surveys (Eaton, Anthony, Tepper, & Dryman, 1992), the response bias connected to psychopathology has not been extremely strong. Persons with psychiatric diagnoses are not more likely to refuse to participate, for example. Persons with cognitive impairment are more likely to die during a follow-up interval, and persons with antisocial personality disorder, or abuse of illegal drugs, are more likely to change address and be difficult to locate. Differential response bias is particularly threatening to studies with long follow-up periods, such as the British Perinatal Study and the Danish Adoption Study, since there was sizable attrition in both studies.

3.05.7.2 Measurement Bias

Bias in measurement is called invalidity in psychology, and this term is also used in epidemiology. But the study of validity in epidemiology has been more narrowly focused than in psychology. The concentration in epidemiology has been on dichotomous measures, as noted above. The medical ideology has ignored the notion that concepts for disease and pathology might actually be conventions of thought. Where the psychometrician takes as a basic assumption that the true state of nature is not observable, the epidemiologist tends to think of disease as a state whose presence is essentially knowable. As a result, discussion of face validity, content validity, or construct validity are rare in epidemiologic research. Instead the focus has been on sensitivity and specificity, which are two aspects of criterion validity (also a term not used much in epidemiologic research).

Sensitivity is the proportion of true cases that are identified as cases by the measure (Table 7). Specificity is the proportion of true noncases that are identified as noncases by the measure. In psychological research, validity is often estimated with a correlation coefficient, but this statistic is inappropriate because the construct of disease is dichotomous and differences in rarity of the disorder will constrain the value of the correlation coefficient. Furthermore, use of sensitivity and specificity has the advantage over correlation that it forces quantification of both types of error, that is, false-positive and false-negative error. These errors, and the calibration of the measurement to adapt to them, depend heavily on the prevalence of the disorder, on the importance of locating cases, and on the expense of dealing with those cases that are located. Choice of a threshold to define disorder as present or absent has important consequences, and is aided by detailed study of the effects of different thresholds (sometimes termed response operating characteristic (ROC) analysis, as in Murphy, 1987). There are simple procedures for correcting prevalence estimates according to the sensitivity and specificity of the measurement (Rogan & Gladen, 1978). Procedures for correcting measures of association, such as the odds ratio, are more complicated since they depend on the precise study design.

Bias also exists in the measurement of exposure. The epidemiologist's tendency to categorical measurement leads to the term "misclassification" for this type of bias. A well-known example is the study of Lilienfeld and Graham (1958: cited in Schlesselman, 1982, pp. 137–138), which compared male patients' declarations as to whether they were circumcised to the results of a doctor's examination. Of the 84 men judged to be circumcised by the doctor (the "gold standard" in this situation), only 37 reported being circumcised (44% sensitivity). Eighty-nine of the 108 men who were not circumcised in the view of the doctor reported not being circumcised (82% specificity). In psychological research, the exposures are often subjective psychological happenings, such as emotions, or objective events recalled by the subject, such as life events, instead of, for example, residence near a toxic waste dump, as might be the putative exposure in a study of cancer. The importance of psychological exposures, or subjective reporting of exposures, threatens the validity of the case–control design in psychiatric epidemiology, and may be one reason it has been used so little. The cases in a case–control study by definition have a disease or problem which the controls do not. In any kind of case–control study where the measure of exposure is based on recall by the subjects, the cases may be more likely than controls to recall exposures, because they wish to explain the occurrence of the disease. In the study of depression in London, depressed women may be more likely to recall a difficult life event that happened earlier in their lives, because of their current mood, than women who are not depressed; or depressed women may magnify the importance of a given event which actually did occur. These problems of recall raise the importance of strictly prospective designs in psychological epidemiological research.

3.05.8 CONCLUSION: THE FUTURE OF PSYCHOLOGY IN EPIDEMIOLOGY

Epidemiology is developing rapidly in ways that will promote effective collaboration with psychology. The traditional interest of psychologists in health as well as illness links up to epidemiologists' growing interest in the development of host resistance. The traditional interest of psychologists in phenomenology is beginning to link up with epidemiologists'

Table 7 Sensitivity and specificity.

		True disease status		
		Present	Absent	
Test results	Present	a (True-positives)	b (False-positives)	$a + b$
	Absent	c (False-negatives)	d (True-negatives)	$c + d$
		$a + c$	$b + d$	

Sensitivity = $a / (a + c)$
Specificity = $d / (b + d)$

growing interest in measurement and complex nosology. In statistics, techniques of multivariate analysis are being adapted increasingly well to the developmental perspective. Developments in the field of physiological and biological measurement, including nearly noninvasive assessments of DNA, hormones, and brain structure and functioning, have led to concepts like "molecular epidemiology," which will lead to vast increases in knowledge about how psychological functioning affects diseases across the spectrum of mental and physical illness. Many of these measures are efficient enough to be applied in the context of a large field survey. In a few decades, the concept of the "mind–body split" may be an anachronism. Finally, the increasing use of laptop computers for assistance in assessment of complex human behaviors and traits will increase the utility of questionnaires and interview data. For all these reasons psychologists should look forward to increasingly productive collaborations in the field of epidemiology.

ACKNOWLEDGMENTS

Production of this paper was supported by NIMH grants 47447, and by the Oregon Social Learning Center. The author is grateful to Nina Schooler and Ray Lorion for comments on early drafts.

3.06.1 INTRODUCTION: QUALITATIVE RESEARCH IN CONTEXT

For many researchers the words "qualitative method" spell out psychology's most notorious oxymoron. If there is one thing that qualitative methods are commonly thought to lack it is precisely an adequate methodic way of arriving at findings. Indeed, for much of the twentieth century quantification has been taken as the principle marker of the boundary between a mature scientific psychology and commonsense, intuitive approaches. Since the late 1980s, however, there has been a remarkable increase in interest in qualitative research in psychology. This partly reflects a broader turn to qualitative research across the social sciences, although qualitative research of one kind or another has long been an established feature of disciplines such as education, sociology, and, most prominently, anthropology.

In psychology there is a handbook of qualitative research (Richardson, 1996) as well as a range of volumes and special journal issues whose major focus is on developing qualitative approaches to psychological problems (Antaki, 1988; Bannister, Burman, Parker, Taylor, & Tyndall, 1994; Henwood & Parker, 1995; Henwood & Nicolson, 1995; Smith, Harré, & van Langenhove, 1995). Psychology methods books and collections are increasingly serving up qualitative methods to accompany the more usual diet of experiments, questionnaires, and surveys. At the same time, an increasing permeability of boundaries between the social sciences has provided the environment for a range of trans-disciplinary qualitative methods books including a useful doorstop-sized handbook (Denzin & Lincoln, 1994) and varied edited and authored works (Bogdan & Taylor, 1975; Bryman & Burgess, 1994; Coffey & Atkinson, 1996; Gilbert, 1993; Lofland & Lofland, 1984; Miles & Huberman, 1994; Miller & Dingwall, 1997; Silverman, 1993, 1997a). These general qualitative works are complemented by a mushrooming range of books and articles devoted to specific methods and approaches.

Why has there been this increase in interest in qualitative research? Three speculations are proferred. First, there is a widespread sense that traditional psychological methods have not proved successful in providing major advances in the understanding of human life. Despite regular promissory notes, psychology seems to offer no earth-moving equivalent of the transistor, of general relativity, or of molecular genetics. Second, as is discussed below, views of science have changed radically since the 1950s, making it much harder to paint qualitative researchers, as either antiscientific extremists or merely sloppy humanists. Third, psychology is no longer as insulated from other social sciences as it has been in the past. Of course, for much of its twentieth century existence psychology has been invigorated by infusions from other sciences such as physiology and linguistics. However, in recent years there has been increasing exchange with disciplines where qualitative methods have been more established such as sociology and anthropology. This is reflected in contemporary theoretical developments such as constructionism (Gergen, 1994) and poststructuralism (Henriques, Hollway, Irwin, Venn, & Walkerdine, 1984) that have swept right across the human sciences.

This is, then, an exciting time for qualitative researchers, with new work and new opportunities of all kinds. Yet it should also be emphasised that qualitative research in psychology is in a chaotic state, with a muddle of inconsistent questions and approaches being blended together. Much poor work has involved taking questions formulated in the metaphysics of experimental psychology and attempting to plug them into one or more qualitative methods. At its worst such research peddles unsystematic and untheorized speculations about the influences on some piece of behavior which are backed up with two or three quotes from an interview transcript. This expanding literature and variable quality creates some problems for the production of a useful overview. This chapter selects what are seen as the most coherent and successful qualitative approaches from a range of possibilities, as well as focusing on those approaches which are being used, and have prospects for success, in clinical settings. A range of references is provided for those who wish to follow up alternative methods.

3.06.1.1 Historical Moments in Qualitative Research in Clinical Settings

In one sense a large proportion of twentieth century clinical therapeutic practice was based on qualitative methods. The process of conducting some kind of therapy or counseling with clients and then writing them up as case histories, or using them as the basis for inferences about aspects of the psyche, behavior, or cognitive processes, has been a commonplace of clinical work. Freud's use of case histories in the development of psychoanalytic thinking is probably the most influential. Although it is an approach to clinical knowledge that overwhelmingly eschews quantification, it is hard to say much about its methodic basis. For good or bad, it is dependent on the unformulated skills and intuitions of the therapist/researcher. In the hands of someone as brilliant as Freud the result can be extraordinary; elsewhere the product has often been merely ordinary. The problem for the readers of such research is that they can do little except either take it on trust or disagree. The process through which certain claims are established is not open to scrutiny. However, Freud's study of the case of Little Hans is exceptional in this regard, and so it is briefly worth considering (see Billig, 1998).

Although Freud initially based his arguments for the existence of the Oedipus complex on the interpretation of what patients told him in the course of therapy sessions, he attempted, unusually, to support this part of psychoanalytic theory with more direct evidence. He asked some of his followers to collect observations from their own children. The music critic Max Graf was most helpful in this regard and presented Freud with copious notes on conversations between his son, Hans, and other family members, as well as descriptions of dreams he had recounted. The published case history (Freud, 1977 [1909]) contains more than 70 pages of reports about Hans which Freud describes as reproduced "just as I received them" without "conventional emendations" (1977, pp. 170). Here is an example:

> Another time he [Hans] was looking on intently while his mother undressed before going to bed. "What are you staring like that for?" she asked.
> *Hans*: "I was only looking to see if you'd got a widdler too."
> *Mother*: "Of course. Didn't you know that?"
> *Hans*: "No. I thought you were so big you'd have a widdler like a horse."
> (1977, p. 173)

Freud's fascinating materials and striking interpretations beg many of the questions that have been central to qualitative research ever since. For example, what is the role of Max Graf's expectations (he was already an advocate of Freud's theories) in his selection and rendering of conversations with Hans? How closely do the extracts capture the actual interactions (including the emphasis, nonvocal elements, and so on)? What procedure did Freud use to select the examples that were reproduced from the full corpus? And, most importantly, what is the basis of Freud's interpretations? His interpretations are strongly derived from his theory, as is shown by his willingness to straightforwardly rework the overt sense of the records. Take this example:

> Hans (aged four and a half) was again watching his little sister being given her bath, when he began laughing. On being asked why he was laughing, he replied. "I'm laughing at Hanna's widdler." "Why?" "Because her widdler's so lovely."
> Of course his answer was a disingenuous one. In reality her widdler had seemed to him funny. Moreover, this is the first time he has recognized in this way the distinction between male and female genitals instead of denying it. (1977, p. 184)

Note the way Graf here, and implicitly Freud in his text, treat the laughter as the real indicator of Hans understanding of events, and his overt claim to find his sister's "widdler" lovely as a form of dissembling. Hans is not delighted by the appearance of his sister's genitals but is amused, in line with psychoanalytic theory, by their difference from his own. Again, the issue of how to treat the sense of records of interaction, and what interpretations should be made from them to things going on elsewhere such as actions or cognitions, is a fundamental one in qualitative research (Silverman, 1993).

Some 40 years later another of clinical psychology's great figures, Carl Rogers, advocated the use of newly developed recording technology to study the use of language in psychotherapy itself, with the aim of understanding and improving therapeutic skills. For him such recordings offered "the first opportunity for an adequate study of counseling and therapeutic procedures, based on thoroughly objective data" (Rogers, 1942, p. 433). Rogers envisaged using such recordings in the development of a scale to differentiate the styles of different counselors and studies of the patterns of interaction; for example, "what type of counselor statement is most likely to be followed by statements of the client's feeling about himself?" (1942, p. 434).

Rogers' emphasis on the virtue of recordings was followed up in two major "microscopic" studies of psychotherapeutic discourse. The first by Pettinger, Hockett, and Danehy (1960) focused on the initial portion of an initial interview. A typical page of their study has just a few words of transcript coupled with an extended discussion of their sense. Much of the focus was on the prosodic cues—the intonation and stress—provided in the interview and their contextual significance. Prosody is, of course, a feature of interaction which is almost impossible to reliably capture in *post hoc* notes made by key informants and so highlights the virtue of the new technology. A second study by Labov and Fanshell (1977) also focused on the opening stages of a therapy session, in this case five episodes of interaction from the first 15 minutes of a psychoanalytic therapy session with Rhoda, a 19-year-old girl with a history of anorexia nervosa.

The classic example of ethnographic work in the history of clinical psychology is Goffman's study of the everyday life of a mental hospital published under the title *Asylums* (1961). It is worth noting that although Goffman was a sociologist, the various essays that make up *Asylums* were initially published in psychiatry journals. Rather than utilize tape recording technology to capture the minutiae of some social setting, Goffman used an ethnographic approach. He spent a year working ostensibly as an assistant to the athletic director of a large mental hospital, interacting with patients and attempting to build up an account of the institution as viewed by the patients. His justification for working in this way is instructive for how the strengths and weaknesses of qualitative work have been conceptualized:

> Desiring to obtain ethnographic detail regarding selected aspects of patient social life, I did not employ usual kinds of measurements and controls. I assumed that the role and time required to gather statistical evidence for a few statements would preclude my gathering data on the tissue and fabric of patient life. (1961, p. 8)

As an ethnographic observer, he developed an understanding of the local culture and customs of the hospital by taking part himself. He used the competence generated in this way as the basis for his writing about the life and social organization in a large mental hospital.

3.06.1.2 Background Issues

Before embarking on a detailed overview of some contemporary qualitative approaches to clinical topics there are some background issues that are worth commenting on, as they will help make sense of the aims and development of qualitative approaches. In some cases it is necessary to address issues that have been a long-standing source of confusion where psychologists have discussed the use of qualitative methods.

3.06.1.2.1 Philosophy, sociology, and changing conceptions of science

As noted above, the development of qualitative work in psychology has been facilitated by the more sophisticated understanding of the nature of science provided by philosophers and sociologists since the 1970s. The image of the lone scientist harvesting facts, whose truth is warranted through the cast-iron criterion of replication, has intermittently been wheeled on to defend supposedly scientific psychology against a range of apparently sloppier alternatives. However, this image now looks less than substantial (see Chalmers, 1992; Potter, 1996a; Woolgar, 1988).

The bottom-line status of scientific observation has been undermined by a combination of philosophical analyses and sociological case studies. Philosophers have highlighted the logical relationships between observation statements and theoretical notions (Hesse, 1974; Kuhn, 1962; Popper, 1959). Their argument is that even the simplest of scientific descriptions is dependent on a whole variety of theoretical assumptions. Sociologists have supplemented these insights with studies of the way notions of observations are used in different scientific fields. For example, Lynch (1994) notes the way the term observation is used in astronomy as a loose device for collecting together a range of actions such as setting up the telescope, attaching sensors to it, building up traces on an oscilloscope, converting these into a chart and canvassing the support of colleagues. Knorr Cetina (1997) documents the different notions of observation that appear in different scientific specialities, suggesting that high energy physicists and molecular biologists, for example, work with such strikingly different notions of what is empirical that they are best conceived of as members of entirely different epistemic cultures.

The idea that experimental replication can work as a hard criterion for the adequacy of any particular set of research findings has been shown to be too simple by a range of sociological studies of replication in different fields (Collins, 1981). For example, Collins (1985) has shown that the achievement of a successful replication is closely tied to the conception of what counts as a competent experiment in the first place—and this itself was often as much a focus of controversy as the phenomenon itself. In a study of gravity wave researchers, Collins found that those scientists who believed in gravity waves tended to treat replications that claimed to find them as competent and replications that failed to find them as incompetent. The reverse pattern was true of nonbelievers. What this meant was that replication did not stand outside the controversy as a neutral arbiter of the outcome, but was as much part of the controversy as everything else.

Philosophical and sociological analysis has also shown that the idea that a crucial experiment can be performed which will force the abandonment of one theory and demonstrate the correctness of another is largely mythical (Lakatos, 1970; Collins & Pinch, 1993). Indeed, historical studies suggest that so-called crucial experiments are not merely insufficient to effect the shift from one theory to another, they are often performed, or at least constructed as crucial, after the shift to provide illustration and legitimation (Kuhn, 1977).

Let us be clear at this point. This research does not show that careful observation, skilful replication, and theoretically sophisticated experiments are not important in science. Rather, the point is that none of these things are bottom-line guarantees of scientific progress. Moreover, these sociological studies have suggested that all these features of science are embedded in, and inextricable from, its communal practices. Their sense is developed and negotiated in particular contexts in accordance with *ad hoc* criteria and a wide range of craft skills which are extremely hard to formulate in an explicit manner (Knorr Cetina, 1995; Latour & Woolgar, 1986). The message taken from this now very large body of work (see Jasanoff, Markle, Pinch, & Petersen, 1995) is not that psychologists must adopt qualitative methods, or that qualitative methods will necessarily be any better than the quantitative methods that they may replace or supplement; it is that those psychologists who have argued against the adoption of such methods on the principle that they are unscientific are uninformed about the nature of science.

3.06.1.2.2 Investigatory procedures vs. justificatory rhetoric

There are a number of basic linguistic and metatheoretical difficulties in writing about qualitative methods for psychologists. Our terminology for methodological discussion—reliability, validity, sampling, factors, variance, hypothesis testing, and so on—has grown up with the development of quantitative research using experiments and surveys. The language has become so taken-for-granted that it is difficult to avoid treating it as obvious and natural. However, it is a language that is hard to disentangle from a range of metatheoretical assumptions about the nature of behavior and processes of interaction. Traditional psychology has become closely wedded to a picture of factors and outcomes which, in turn, cohabits with the multivariate statistics which are omnipresent where data is analyzed. For some forms of qualitative research, particularly most discourse and ethnographic work, such a picture is inappropriate. This does not mean that such research is incoherent or unscientific, merely that it should not be construed and evaluated using the family of concepts whose home is experimental journal articles. Likewise the psychological model of hypothesis testing is just one available across the natural and human sciences. Qualitative research that utilizes theoretically guided induction, or tries to give a systematic description of some social realm, should not be criticized on the grounds that it is unscientific, let alone illegitimate. Ultimately, the only consistent bottom line for the production of excellent qualitative work is excellent scholarship (Billig, 1988).

Another difference between traditional quantitative and qualitative work is that in the traditional work the justification of research findings is often taken to be equivalent to the complete and correct carrying out of a set of codified procedures. Indeed, methods books are often written as if they were compendia of recipes for achieving adequate knowledge. Sampling, operationalization of variables, statistical tests, and interpretation of significance levels are discussed with the aid of tree diagrams and flow charts intended to lead the apprentice researcher to the correct conclusion. In one sense, much qualitative work is very different to this, with the procedures for justifying the research claims being very different to the procedures for producing the work. Thus, the manner in which a researcher arrives at some claims about the various functions of "mm hm's" in psychiatric intake interviews, say, may be rather different from the manner in which they justify the adequacy of the analysis. Yet, in another sense the difference between qualitative and quantitative research is more apparent than real, for studies of the actual conduct of scientists following procedural rules of method show that such rules require a large amount of tacit knowledge to make them understandable and workable, and that they are often more of a rhetorical device used to persuade other scientists than an actual constraint on practice (Gilbert & Mulkay, 1984; Polyani, 1958). As Collins (1974) showed in an innovative ethnographic study, when a group of scientists wrote a paper offering the precise technical specification of how to make a new laser, the only people who were able to build a working laser of their own had actually seen one built; just reading the paper was not enough.

This presents something of a dilemma for anyone writing about qualitative methods. Should they write to help people conduct their research so as better to understand the world, or should they work to provide the sorts of formalized procedural rules that can be drawn on in the methods sections of articles to help persuade the psychologist reader? In practice, most writing does some of each. However, the difficulty that psychologists often report when attempting qualitative work is probably symptomatic of the failure to fully explicate the craft skills that underpin qualitative work.

3.06.1.2.3 Quality and quantity

There are different views on how absolute the quantity/quality divide is. Arguments at different levels of sophistication have been made for future integration of qualitative and quantitative research (Bryman, 1988; Silverman, 1993). It is undoubtedly the case that at times proponents of both quantitative and qualitative research have constructed black and white stereotypes with little attempt at dialog (although a rare debate about the relative virtues of quantitative and qualitative research on the specific topic of attitudes towards mental hospitalisation is revealing—Weinstein, 1979, 1980; Essex et al., 1980). It is suggested that quantification is perfectly appropriate in a range of situations, dependent on appropriate analytic and theoretical judgements.

In many other research situations the goal is not something that can be achieved through counting. For example, if the researcher is explicating the nature of "circular questioning" in Milan School Family Therapy, that goal is a prerequisite for a study which considers the statistical prevalence of such questioning. Moreover, there are arguments for being cautious about quantification when studying the sorts of discursive and interactional materials which have often been central to qualitative research because of distortions and information loss that can result (see Schegloff, 1993, and papers in Wieder, 1993). Some of the grounds for caution come from a range of qualitative studies of quantification in various clinical settings (Ashmore, Mulkay, & Pinch, 1989; Atkinson, 1978; Garfinkel, 1967a; Potter, Wetherell, & Chitty, 1991).

3.06.1.3 Qualitative Research and Theory

It is hard to overestimate how close the relationship is between the theories, methods, and questions used by psychologists. Theories specify different positions on cognition and behavior, different notions of science, different views of the role of action and discourse, different understandings of the role of social settings, and, most fundamentally, different objects for observation.

For both psychoanalytic theory and most of the mass of theories and perspectives that make up modern cognitivism the objects of observation are hypothetical mental entities (the Oedipus complex, attributional heuristics). Psychoanalytic researchers have generally preferred to engage in an interpretative exercise of reconstructing those entities from the talk of patients undergoing therapy. Cognitive psychologists have typically used some hypothetico-deductive procedure where predictions are checked in experiments which investigate, say, the attributional style of people classified as depressed. Note that in both of these cases they are using people's discourse—talk in the therapy session, written responses to a questionnaire—yet in neither case is the discourse as such of interest. In contrast, for researchers working with different perspectives such as social constructionism or discursive psychology, the talk or writing itself, and the practices of which it is part, is the central topic. For these researchers there is a need to use procedures which can make those practices available for study and allow their organization to be inspected and compared.

To take another example, behaviorist psychologists have done countless studies on the effects of particular regimes of reward and punishment on target behaviors such as compulsive hand washing. However, such studies are typically focused on outcomes and statistical associations, whereas a theoretical perspective such as symbolic interactionism or, to give a more psychological example, Vygotskyan activity theory, encourage a more ethnographic examination of the settings in which rewards are administered and of the sense that those behaviors have in their local context

Without trying to flesh out these examples in any detail, the important practical point they make is that it is a mistake to attempt simply to import a question which has been formulated in the problematics of one theoretical system, and attempt to answer it using a method developed for the problematics of another. The failure to properly conceptualize a research question that fits with the research method is a major source of confusion when psychologists start to use qualitative methods.

3.06.1.4 Boundaries of Qualitative Research and Coverage of the Current Chapter

What distinguishes qualitative research from quantitative? And what qualitative approaches are there? These questions are not as straightforward as they seem. In the past the qualitative/quantitative distinction has sometimes been treated as the equivalent of the distinction between research that produces objective and subjective knowledge—a distinction which makes little sense in the light of recent sociology and philosophy of science. Sometimes certain approaches using numbers have been treated as qualitative. For example, content analysis has occasionally been treated as a qualitative method because it is used to deal with "naturally occurring" objects such as diaries, novels, transcripts of meetings, and so on. Content analysis was meant to eliminate many of the potential "reactive" effects that bedevil social research and thereby avoid the problem in experimental and survey research, of how findings relate to what goes on in the real world; for these are records of (indeed, examples of) what is actually going on. However, in this chapter content analysis is treated as quantitative, and therefore outside the scope of this survey, on the grounds that it (i) transforms phenomena into numerical counts of one kind or another and (ii) typically attempts to statistically relate these counts to some broader factors or variables. For useful introductions to content analysis related to psychological topics see Holsti (1969) and Krippendorf (1980).

For similar reasons repertory grid analysis associated with personal construct theory, and the "Q" methodology developed by William Stephenson, have sometimes been treated as qualitative. The rationale for this was probably that they were often focused on understanding the reasoning or cognitive organization of single individuals rather than working exclusively from population statistics. However, as they involve quantitative manipulation of elicited responses from participants they will not be dealt with here. The ideographic/nomathetic distinction will be treated as orthogonal to the qualitative/quantitative one! For accessible introductions to these approaches, see Smith (1995) on repertory grid methods and Stainton Rogers (1995) on Q methodology.

In addition to these methods which are excluded as not properly qualitative, a wide range of methods have not been discussed which nevertheless satisfy the criterion of being at least minimally methodic and generally eschewing quantification. For simplicity, Table 1 lists nine methods or approaches which have been excluded, along with one or two references that would provide a good start point for any researcher who was interested in learning more about them. It would take some time to make explicit the reasons for excluding all of them. Generally, the problem is that they have not been, and are unlikely to be in the future, particularly useful for studying problems in the area of clinical psychology (e.g., focus groups—although, see Piercy & Nickerson, 1996). In some cases, the approaches are not coherent enough to warrant discussion. In others, their central problematics are better addressed by the approaches that are discussed.

The most controversial exclusion is probably humanistic methods given that humanistic psychology developed in settings which had a broad emphasis on therapy and psychological well-being. It is suggested that the romanticism of much humanistic psychology is attractive, but ultimately unconvincing. However, it is often, quite legitimately, more concerned with developing participants' skills and sensitivity than developing propositional claims and arguments; as such it is often offering a set of techniques for expanding human potential rather than developing methods for research. Feminist methods are excluded, despite an appreciation of the importance of feminist issues in clinical settings, because the arguments for the existence of specifically feminist methods (as opposed to theories or arguments) are not convincing. This is particularly true where such claims give a major epistemological role for experience or intuition (Ellis, Kiesinger, & Tillmann-Healy, 1997). These are topics for decomposition and analysis rather than bottom-lines for knowledge. For some arguments in both directions on this topic see Gelsthorpe (1992), Hammersley (1992), Ramazanoglu (1992), and Wilkinson (1986).

Finally, it should be stressed that qualitative work is not seen as having some overall coherence. Quite the contrary, it is fragmented and of highly variable quality. Nor is some overall coherence seen as a desirable goal. Those workers who talk of a qualitative paradigm (Guba & Lincoln, 1994, Reason & Rowan, 1981) unhelpfully blur over a range of theoretical and metatheoretical differences (see Henwood & Pidgeon, 1994).

3.06.2 GROUNDED THEORY

Grounded theory has the most clear-cut origin of any of the approaches discussed here. The term was coined by two sociologists in an influential book: *The discovery of grounded theory* (Glaser & Strauss, 1967). Some of its key features and concerns were a product of its birthplace within sociology, where it was developed to counter what the authors saw as a preoccupation, on the one hand, with abstract grand theories and, on the other, with testing those theories through large scale quantitative studies. Grounded theory was intended to link theoretical developments (conceived as plausible relations among concepts and sets of concepts—Strauss & Corbin, 1994) more closely to the particulars of settings, to ground

middle range theories in actual qualitative data rather than to start from preconceived hypotheses. It is important to stress that grounded theory is not a theory as such, rather it is an approach to theorising about data in any domain. Moreover, since its inception in the 1960s, work on the theory ladenness of data has made the idea of "grounding" theory increasingly problematic.

Much grounded theory research has been done outside of psychology; however, psychologists have become increasingly interested in the approach in general (Charmaz, 1995; Henwood and Pidgeon, 1995; Pidgeon, 1996; Pidgeon and Henwood, 1996; Rennie, Phillips & Quartaro, 1988), and have carried out specific studies in health (Charmaz, 1991, 1994) and clinical (Clegg, Standen, & Jones, 1996) settings.

3.06.2.1 Questions

Grounded theory is designed to be usable with a very wide range of research questions and in the context of a variety of metatheoretical approaches. Rather like the statistical analyses that psychologists are more familiar with, it deals with patterns and relationships. However, these are not relationships between numbers but between ideas or categories of things, and the relationships can take a range of different forms. In some respects the procedures in grounded theory are like the operation of a sophisticated filing system where entries are cross-referenced and categorized in a range of different ways. Indeed, this is one qualitative approach that can be effectively helped by the use of computer packages such as NUDIST, which was itself developed to address grounded theory notions.

Grounded theory has proved particularly appropriate for studying people's understandings of the world and how these are related to their social context. For example, Turner (1994; Turner & Pidgeon, 1997) has used grounded theory to attempt to explain the origins of manmade disasters like fires and industrial accidents; Charmaz (1991) has studied the various facets that make up people's experience of chronic illness; Clegg, Standen, and Jones (1996) focused on the staff members' understanding of their relationship with adults with profound learning disabilities. In each case, a major concern was to incorporate the perspectives of the actors as they construct their particular social worlds. Grounded theory methods can help explicate the relation of actions to settings (how does the behavior of key personnel in the evolution of a major fire follow from their individual understanding of events and physical positioning?); it can be used for developing typologies of relevant phenomena (in what different ways do sufferers of chronic illness conceptualize their problem?); and it can help identify patterns in complex systems (how does the information flowing between social actors help explain the development of a laboratory smallpox outbreak?).

Like most of the qualitative approaches discussed here, grounded theory is not well suited to the kinds of hypothesis testing and outcome evaluation that have traditionally been grist to the mill of clinical psychology, because of its open-ended and inductive nature. Although the researcher is likely to come to a topic with a range of more or less explicit ideas, questions, and theories, it is not necessary for any or all of these to be formally stated before research gets under way. The approach can start with a specific problem or it may be more directed at making sense of an experience or setting.

Grounded theory can be applied to a range of different textual materials such as documents, interview transcripts and records of interaction, and this makes it particularly suitable for certain kinds of questions. It can deal with records which exist prior to the research and it can deal with materials specifically collected. The processes of coding allow quite large amounts of material to be dealt with. For example, while Turner studied a single (lengthy) official report of a major fire in a holiday complex, Charmaz studied 180 interviews with 90 different people with chronic illnesses. The requirement is only that the material can be coded.

3.06.2.2 Procedures

The procedures for conducting grounded theory work are straightforward to describe, if less so to follow in practice. Pidgeon and Henwood (1996, p. 88) provide a useful diagram to explicate the process (Figure 1).

3.06.2.2.1 Materials

In line with the general emphasis on participants' perspectives and on understanding patterns of relationships, researchers often attempt to obtain rich materials such as documents and conversational, semistructured interviews. These may be supplemented by participant observation in the research domain, generating fieldnotes which can be added to other data sets or simply used to improve the researcher's understanding so they can better deal with the other materials.

After data is collected and stored the intensive process that is most characteristic of grounded theory is performed. This involves coding the data, refining the coding and identifying links between categories, and writing "memos" which start to capture theoretical concepts and relationships.

3.06.2.2.2 Coding

Different grounded theory researchers approach coding in different ways. For example, it can involve generating index cards or making annotations next to the relevant text. The researcher works through the text line by line, or paragraph by paragraph, labeling the key concepts that appear. Charmaz (1995, p. 38) suggests a series of specific questions that are useful for picking out the key concepts:

(i) What is going on?
(ii) What are the people doing?
(iii) What is the person saying?
(iv) What do these actions and statements take for granted?
(v) How do structure and context serve to support, maintain, impede, or change these actions and statements?

More broadly, Pidgeon and Henwood suggest that this phase of coding is answering the question: "what categories or labels do I need in order to account for what is of importance to me in this paragraph?" (1996, p. 92).

Such coding is intensive and time consuming. For example, Table 2 shows an example by Charmaz of line-by-line coding of just a brief fragment of one of her 180 interviews. Note the way that the interview fragment is coded under a number of different topics. There is no requirement in grounded theory that categories apply exclusively.

3.06.2.2.3 Method of constant comparison

Coding is not merely a matter of carefully reading and labeling the materials. As the coding continues the researcher will be starting to identify categories that are interesting or relevant to the research questions. They will refine their indexing system by focused coding which will pick out all the instances from the data coded as, for example "avoiding disclosure." When such a collection has been produced the researcher can focus on the differences in the use of this category according to the setting or the actors involved. This is what grounded theorists refer to as the "method of constant comparison." In the course of such comparisons the category system may be reworked; some categories will be merged together and others will be broken up, as the close reading of the data allows an increasingly refined understanding.

Table 2 Line-by-line coding.

Coding	*Interview*
Shifting symptoms, having inconsistent days	If you have lupus, I mean one day it's my liver; one day it's my joints; one day it's my head, and
Interpreting images of self given by others	it's like people really think you're a hypochondriac if you keep complaining about
Avoiding disclosure	different ailments. . . . It's like you don't want to say anything because people are going to start
Predicting rejection	thinking, you know, "God, don't go near her,
Keeping others unaware	all she is—is complaining about this."

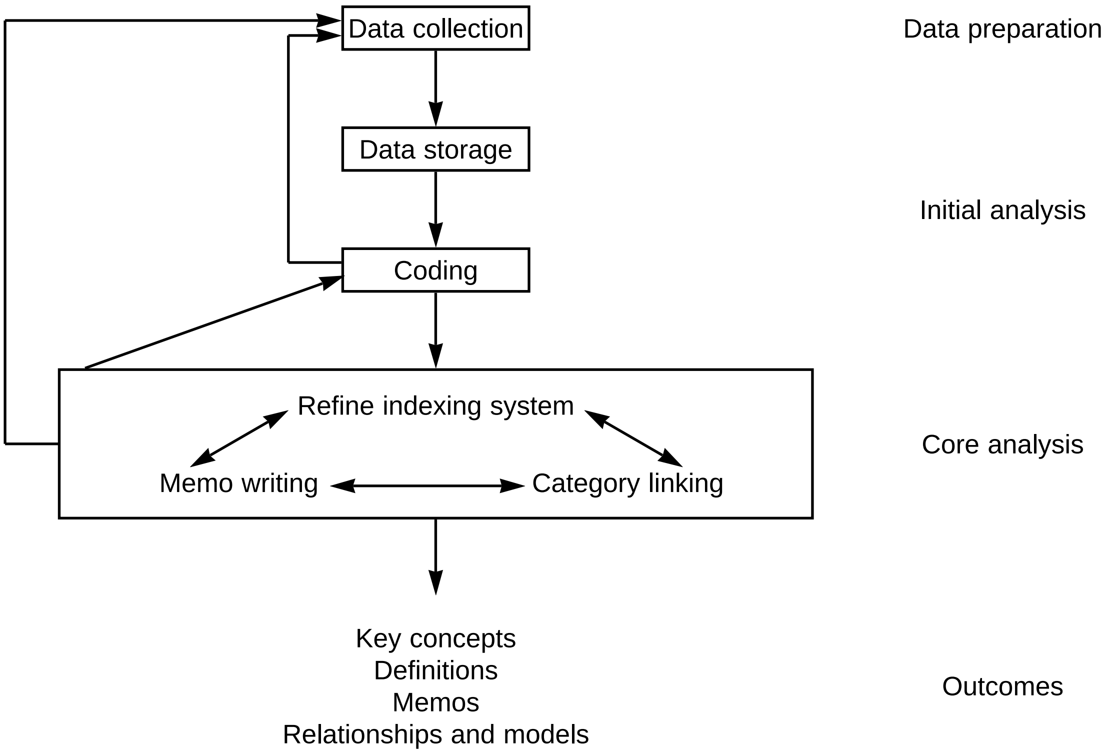

Figure 1 Procedures for conducting grounded theory research.

3.06.2.2.4 Memo writing

Throughout this stage of coding and comparison grounded theorists recommend what they call memo writing. That is, writing explicit notes on the assumptions that underly any particular coding. Memo writing is central to the process of building theoretical understandings from the categories, as it provides a bridge between the categorization of data and the writing up of the research. In addition to the process of refining categories, a further analytic task involves linking categories together. The goal here is to start to model relationships between categories. Indeed, one possibility may be the production of a diagram or flow chart which explicitly maps relationships.

As Figure 1 makes clear, these various elements in grounded theory analysis are not discrete stages. In the main phase of the analysis, refining the indexing system is intimately bound up with the linking of categories, and memo writing is likely to be an adjunct to both. Moreover, this analysis may lead the researcher back to the basic line-by-line coding, or even suggest the need to collect further material for analysis.

3.06.2.2.5 Validity

There is a sense in which the general methodological procedures of grounded theory are together designed to provide a level of validation as they force a thoroughgoing engagement with the research materials. Line-by-line coding, constant comparison, and memo writing are all intended to ensure that the theoretical claims made by the analyst are fully grounded in the data. That, after all, was the original key idea of grounded theory. However, some specific procedures of validation have been proposed.

Some grounded theorists have suggested that respondent validation could be used as a criterion. This involves the researcher taking back interpretations to the participants to see if they are accepted. The problem with such an approach is that participants may agree or disagree for a range of social reasons or they may not understand what is being asked of them. Other approaches to validation suggest that research should be generative, that is, facilitate further issues and questions; have rhetorical power, that is, prove effective in persuading others of its effectiveness; or that there could be an audit trail which would allow another researcher to check how the conclusions were reached (Henwood & Pidgeon, 1995; Lincoln & Guba, 1985).

3.06.2.3 Example: Clegg, Standen, and Jones (1996)

There is no example in clinical psychology of the sorts of full-scale grounded theory study that Charmaz (1991) conducted on the experience of illness or Glaser and Strauss (1968) carried out on hospital death. Nevertheless, a modest study by Clegg et al. (1996) of the relationships between staff members and adults with profound learning disabilities illustrates some of the potential of grounded theory for clinical work.

In line with the grounded theory emphasis on the value of comparison, 20 staff members from four different residential settings were recruited. Each member of staff was videotaped during eight sessions of interaction with a single client that they had known for over three months. Each staff member was subsequently interviewed about their work, their relationship with the client, a specific experience with the client, and their understanding of the client's view of the world. These conversational interviews were tape recorded and transcribed, and form the data for the major part of the study.

The study followed standard grounded theory procedures in performing a range of codings developing links between categories and building up theoretical notions from those codings. The range of different outcomes of the study is typical of grounded theory. In the first place, they identify four kinds of relationships that staff may have with clients: provider (where meeting of the client's needs is primary); meaning-maker (where making sense of the client's moods or gestures is primary); mutual (where shared experience and joy at the client's development is primary); companion (where merely being together is treated as satisfying). The authors go on to explore the way different settings and different client groups were characterized by different relationships. Finally, they propose that the analysis supports four propositions about staff–client relationships: some types of relationship are better than others (although this will vary with setting and client); staff see the balance of control in the relationship as central; families can facilitate relationships; professional networks create dilemmas.

3.06.2.4 Virtues and Limitations

Grounded theory has a range of virtues. It is flexible with respect to forms of data and can be applied to a wide range of questions in varied domains. Its procedures, when followed fully, force the researcher into a thorough engagement with the materials; it encourages a slow-motion reading of texts and transcripts that should avoid the common qualitative research trap of trawling a set of transcripts for quotes to illustrate preconceived ideas. It makes explicit some of the data management procedures that are commonly left inexplicit in other qualitative approaches. The method is at its best where there is an issue that is tractable from a relatively common sense actor's perspective. Whether studying disasters, illness, or staff relationships, the theoretical notions developed are close to the everyday notions of the participants. This makes the work particularly suitable for policy implementation, for the categories and understandings of the theory are easily accessible to practitioners and policy makers.

Some problems and questions remain, however. First, although there is a repeated emphasis on theory—after all, it is in the very name of the method—the notion of theory is a rather limited one strongly influenced by the empiricist philosophy of science of the 1950s. The approach works well if theory is conceived in a limited manner as a pattern of relationships between categories, but less well if theories are conceived of as, say, models of underlying generative mechanisms (Harré, 1986).

Second, one of the claimed benefits of grounded theory work is that it works with the perspective of participants through its emphasis on accounts and reports. However, one of the risks of processes such as line-by-line coding is that it leads to a continual pressure to assign pieces of talk or elements of texts to discrete categories rather than seeing them as inextricably bound up with broader sequences of talk or broader textual narratives. Ironically this can mean that instead of staying with the understandings of the participants their words are assigned to categories provided by the analyst.

Third, grounded theorists have paid little attention to the sorts of problems in using textual data that ethnomethodologists and discourse analysts have emphasised (Atkinson, 1978; Gilbert & Mulkay, 1984; Silverman, 1993; Widdicombe & Wooffitt, 1995). For example, how far is the grounding derived not from theorizing but from reproducing common sense theories as if they were analytic conclusions? How far are Clegg's et al. (1996) staff participants, say, giving an accurate picture of their relationships with clients, and how far are they drawing on a range of ideas and notions to deal with problems and work up identities in the interview itself?

Some practitioners are grappling with these problems in a sophisticated manner (Pidgeon & Henwood, 1996). As yet there is not a large enough body of work with clinical materials to allow a full evaluation of the potential of this method. For more detailed coverage of grounded theory the reader should start with the excellent introductions by Pidgeon (1996) and Pidgeon and Henwood (1996); Charmaz (1991) provides a full scale research illustration of the potential of grounded theory; Rafuls and Moon (1996) discuss grounded theory in the context of family therapy; and, despite its age, Glaser and Strauss (1967) is still an informative basis for understanding the approach.

3.06.3 ETHNOGRAPHY AND PARTICIPANT OBSERVATION

Ethnography is not a specific method so much as a general approach which can involve a number of specific research techniques such as interviewing and participant observation. Indeed, this has been a source of some confusion as rather different work is described as ethnography in anthropology, sociology, and other disciplines such as education or management science. The central thrust of ethnographic research is to study people's activities in their natural settings. The concern is to get inside the understanding and culture, to develop a subtle grasp of how members view the world, and why they act as they do. Typically, there is an emphasis on the researcher being involved in the everyday world of those who are being studied. Along with this goes a commitment to working with unstructured data (i.e., data which has not been coded at the point of data collection) and a tendency to perform intensive studies of small numbers of cases. Ethnography is not suited to the sorts of hypothetico-deductive procedures that are common in psychology.

Two important tendencies in current ethnographic work can be seen in their historical antecedents in anthropology and sociology. In the nineteenth century, anthropology often involved information collected by colonial administrators about members of indigenous peoples. Its use of key informants and its focus on revealing the details of exotic or hidden cultures continue in much work. Sociologists of the "Chicago School" saw ethnography as a way of revealing the lives and conditions of the US underclass. This social reformism was married to an emphasis on understanding their participants' lives from their own perspective.

3.06.3.1 Questions

Ethnography comes into its own where the researcher is trying to understand some particular sub-cultural group in a specific setting. It tends to be holistic, focusing on the entire experience participants have of a setting, or their entire cosmology, rather than focusing on discrete variables or phenomena. This means that ethnographic questions tend to be general: What happens in this setting? How do this group understand their world? In Goffman's (1961) *Asylums* he tried to reveal the different worlds lived by the staff and inmates, and to describe and explicate some of the ceremonies that were used to reinforce boundaries between the two groups. A large part of his work tracked what he called the "moral careers" of inmates from prepatient, through admission, and then as inpatients. Much of the force and influence of Goffman's work derived from its revelations about the grim "unofficial" life lived by patients in large state mental hospitals in the 1950s. In this respect it followed in the Chicago school tradition of exposé and critique. Rosenhan's (1973) classic study of hospital admission and the life of the patient also followed in this tradition. Famously it posed the question of what was required to be diagnosed as mentally ill and then incarcerated, and discovered that it was sufficient to report hearing voices saying "empty," "hollow," and "thud." This "pseudopatient" study was designed with a very specific question about diagnostic criteria in mind; however, after the pseudopatients were admitted they addressed themselves to more typically ethnographic concerns, such as writing detailed descriptions of their settings, monitoring patient contact with different kinds of staff, and documenting the experience of powerlessness and depersonalization.

Goffman's and Rosenhan's work picks up the ethnographic traditions of revealing hidden worlds and providing a basis for social reform. Jodelet (1991) illustrates another analytic possibility by performing an intensive study of one of the longest running community care schemes in the world, the French colony of Ainay-le-Château where mental patients live with ordinary families. Again, in line with the possibilities of ethnography, she attempted to explore the whole setting, including the lives of the patients and their hosts and their understandings of the world. Her work, however, is notable for showing how ethnography can explore the representational systems of participants and relate that system to the lives of the participants. To give just one small example, she shows the way the families' representation of a close link between madness and uncleanliness relates to practices such as taking meals separately from the lodgers.

Another topic for ethnographic work has been the practice of psychotherapy itself (Gubrium, 1992; Newfield, Kuehl, Joanning, & Quinn, 1990, 1991). These studies are interested in the experience of patients in therapy and their conceptions of what therapy is, as well as the practices and conceptions of the therapists. Such studies do not focus exclusively on the interaction in the therapy session itself, but on the whole setting.

Although ethnography is dependent on close and systematic description of practices it is not necessarily atheoretical. Ethnographic studies are often guided by one of a range of theoretical conceptions. For example, Jodelet's (1991) study was informed by Moscovici's (1984) theory of social representations and Gubrium's (1992) study of family therapy was guided by broader questions about the way the notion of family and family disorder are constructed in Western society. Ethnography has sometimes been treated as particularly appropriate for feminist work because of the possibility of combining concerns with experience and social context (e.g., Ronai, 1996).

3.06.3.2 Procedures

Ethnography typically involves a mix of different methods with interviews and participant observation being primary, but often combined with nonparticipant observation and the analysis of documents of one kind or another. Such a mixture raises a large number of separate issues which will only be touched on here. There are whole books on some elements of ethnographic work such as selecting informants (Johnson, 1990), living with informants (Rose, 1990), and interpreting ethnographic writings (Atkinson, 1990). The focus here is on research access, field relations, interviewing, observing, fieldnotes, and analysis (see Ellen, 1984; Fetterman, 1989; Fielding, 1993; Hammersley & Atkinson, 1995; Rachel, 1996; Toren, 1996; Werner & Schoepfle, 1987).

3.06.3.2.1 Access

Research access is often a crucial issue in ethnography, as a typical ethnographic study will require not only access to some potentially sensitive group or setting but may involve the researcher's bodily presence in delicate contexts. Sitting in on a family therapy session, for example, may involve obtaining consent from a range of people who have different concerns and has the potential for disrupting, or at least subtly changing, the interaction that would have taken place. There are only restricted possibilities for the ethnographer to enter settings with concealed identities, as Goffman did with his mental hospital study, and Rosenhan's pseudopatients did. Moreover, such practices raise a host of ethical and practical problems which increasingly lead ethnographers to avoid deception. Access can present another problem in sensitive settings if it turns out that it is precisely unusual examples where access is granted, perhaps because the participants view them as models of good practice.

3.06.3.2.2 Field relations

Field relations can pose a range of challenges. Many of these follow from the nature of the participation of the researcher in the setting. How far should researchers become full participants and how far should they stay uninvolved observers? The dilemma here is that much of the power of ethnography comes from the experience and knowledge provided by full participation, and yet such participation may make it harder to sustain a critical distance from the practices under study. The ethnographer should not be converted to the participants' cultural values; but neither should they stay entirely in the Martian role that will make it harder to understand the subtle senses through which the participants understand their own practices. Field relations also generate many of practical, prosaic, but nevertheless important problems which stem from the sheer difficulty of maintaining participant status in an unfamiliar and possibly difficult setting for a long period of time. At the same time there are a whole set of skills required to do with building productive and harmonious relationships with participants.

3.06.3.2.3 Fieldnotes

One of the central features of participant observation is the production of fieldnotes. Without notes to take away there is little point in conducting observation. In some settings it may be possible to take notes concurrently with the action but often the researcher will need to rely on their memory, writing up notes on events as soon as possible after they happened. A rule of thumb is that writing up fieldnotes will take just as much time as the original period of observation (Fielding, 1993). In some cases it may be possible to tape record interaction as it happens. However, ethnographers have traditionally placed less value on recording as they see the actual process of note taking as itself part of the process through which the researcher comes to understand connections between processes and underlying elements of interaction.

Ethnographers stress that fieldnotes should be based around concrete descriptions rather than consisting of abstract higher-order interpretations. The reason for this is that when observation is being done it may not yet be clear what questions are to be addressed. Notes that stay at low levels of inference are a resource that can be used to address a range of different questions. Fielding argues that fieldnotes are expected:

> to provide a running description of events, people and conversation. Consequently each new setting observed and each new member of the setting

> merits description. Similarly, changes in the human or other constituents of the setting should be recorded. (1993, p. 162)

It is also important to distinguish in notes between direct quotation and broad précis of what participants are saying. A final point emphasised by ethnographers is the value of keeping a record of personal impressions and feelings.

3.06.3.2.4 Interviews

Ethnographers make much use of interviews. However, in this tradition interviews are understood in a much looser manner than in much of psychology. Indeed, the term interview may be something of a misnomer with its image of the researcher running through a relatively planned set of questions with a single passive informant in a relatively formal setting. In ethnography what is involved is often a mix of casual conversations with a range of different participants. Some of these may be very brief, some extended, some allowing relatively formal questioning, others allowing no overt questioning. In the more formal cases the interview may be conducted with a planned schedule of questions and the interaction is recorded and transcribed.

3.06.3.2.5 Analysis

There is not a neat separation of the data collection and analytic phases of ethnographic research. The judgements about what to study, what to focus on, which elements of the local culture require detailed description, and which can be taken for granted, are already part of analysis. Moreover, it is likely that in the course of a long period of participant observation, or a series of interviews, the researcher will start to develop accounts for particular features of the setting, or begin to identify the set of representations shared by the participants. Such interpretations are refined, transformed, and sometimes abandoned when the fieldwork is completed and the focus moves on to notes and transcripts.

Fielding (1993, p. 192) suggests that the standard pattern of work with ethnographic data is straightforward. The researcher starts with the fieldnotes and transcripts and searches them for categories and patterns. These themes form a basis for the ethnographic account of the setting, and they also structure the more intensive analysis and probably the write-up of the research. The data will be marked or cut up (often on computer text files) to collect these themes together. In practice, the ethnographer is unlikely to attempt a complete account of a setting, but will concentrate on a small subset of themes which are most important or which relate to prior questions and concerns.

The analytic phase of ethnography is often described in only the sketchiest terms in ethnography guidebooks. It is clear that ethnographers often make up their own ways of managing the large amount of materials that they collect, and for using that material in convincing research accounts. At one extreme, ethnography can be considered an approach to develop the researcher's competence in the community being studied—they learn to be a member, to take part actually and symbolically, and they can use this competence to write authoritatively about the community (Collins, 1983). Here extracts from notes and interview transcripts become merely exemplars of the knowledge that the researcher has gained through participation. At the other extreme, ethnography blurs into grounded theorizing, with the notes and transcripts being dealt with through line-by-line coding, comparison of categories, and memo writing. Here the researcher's cultural competence will be important for interpreting the material, but the conclusions will ultimately be dependent on the quality of the fieldnotes and transcripts and what they can support.

3.06.3.2.6 Validity

One of the virtues of ethnography is its rich ecological validity. The researcher is learning directly about what goes on in a setting by observing it, by taking part, and/or by interviewing the members. This circumvents many of the inferences that are needed in extrapolating from more traditional psychological research tools—questionnaires, experimental simulations—to actual settings. However, the closeness of the researcher to the setting does not in itself ensure that the research that is produced will be of high quality.

The approach to validity most often stressed by ethnographers is triangulation. At the level of data this involves checking to see that different informants make the same sorts of claims about actions or events. At the level of method, it involves checking that conclusions are supported by different methods, for example, by both interviews and observation. However, triangulation is not without its problems. Discourse researchers have noted that in practice the sheer variability in and between accounts makes triangulation of only limited use (Potter & Wetherell, 1987) and others have identified conceptual problems in judging what a successful triangulation between methods would be (Silverman, 1993).

3.06.3.3 Example: Gubrium (1992)

There are only a small number of ethnographies done in clinical settings or on clinical topics. For instance, many of the clinical examples in Newfield, Sells, Smith, Newfield, & Newfield's (1996) chapter on ethnography in family therapy are unpublished dissertations. The body of ethnographic work is small but increasing rapidly. I have chosen Gubrium's (1992) study of family therapy in two institutions as an example because it is a book-length study, and it addresses the therapeutic process itself rather than concentrating solely on the patients' lives in hospital or community care schemes. However, it is important to stress that Gubrium's focus was as much on what the therapy revealed about the way notions of family and order are understood in American culture as in therapeutic techniques and effectiveness. He was concerned with the way behaviours such as truancy take their sense as part of a troubled family and the way service professionals redefine family order as they instigate programmes of rehabilitation.

Gubrium's choice of two contrasting institutions is a commonplace one in ethnography. The small number enables an intensive approach; having more than one setting allows an illuminating range of comparisons and contrasts. In this case one was inpatient, one outpatient; one more middle class than the other; they also varied in their standard approaches to treatment. The virtues of having two field sites shine through in the course of the write-up, although it is interesting to note that the selection was almost accidental as the researcher originally expected to be successful in gaining access to only one of the institutions.

The fieldwork followed a typical ethnographic style of spending a considerable amount of times at the two facilities, talking to counselors, watching them at work in therapy sessions, reviewing videos of counseling, and making fieldnotes. The study also drew on a range of documents including patients' case notes and educational materials. In some ways this was a technically straightforward setting for ethnographic observation as many of the participants were themselves university trained practitioners who made notes and videos as part of the general workings of the facilities.

One of the striking differences between this ethnographic study of therapy and a typical process or outcome study is that the therapy is treated as a part of its physical, institutional, and cultural contexts. For instance, time is spent documenting the organization of the reception areas of the two facilities and the way the counselors use the manner in which the families seat themselves in that area as evidence of family dynamics. Gubrium writes about the important role of tissue boxes in both signaling the potential for emotional display and providing practical support when such display occurs:

> I soon realized that tissues were about more than weeping and overall emotional composure during therapy. Tissues mundanely signaled the fundamental reality of the home as locally understood: a configuration of emotional bonds. For Benson [a counselor] their usage virtually put the domestic disorder of the home on display, locating the home's special order in the minutiae of emotional expression. (Gubrium, 1992, p. 26)

The ethnographic focus on events in context means that therapy is treated as a product of actual interactions full of contingency and locally managed understandings. It shows the way abstract notions such as family systems or tough love are managed in practice, and the way the various workers relate to each other as well as to the clients. It provides an insight into the world of family therapy quite different from most other styles of research.

3.06.3.4 Virtues and Limitations

Much of the power of ethnographic research comes from its emphasis on understanding people's actions and representations both in context and as part of the everyday practices that make up their lives, whether they are Yanomami Indians or family therapists. It can provide descriptions which pick out abstract organizations of life in a setting as well as allowing the reader rich access. Ethnography can be used in theory development and even theory testing (Hammersley & Atkinson, 1995). It is flexible; research can follow up themes and questions as they arise rather than necessarily keeping to preset goals.

Ethnographic research can be very time consuming and labor intensive. It can also be very intrusive. Although Gubrium was able to participate in some aspects of family therapy, this was helped by the sheer number of both staff and family members who were involved. It is less easy to imagine participant observation on individual therapy.

One of the most important difficulties with ethnographic work is that the reader often has to take on trust the conclusions because the evidence on which they are based is not available for assessment (Silverman, 1993). Where field notes of observations are reproduced in ethnographies—and this is relatively rare—such notes are nevertheless a ready-theorized version of events. Descriptions of actions and events are always bound up with a range of judgments (Potter, 1996a). Where analysis depends on the claims of key informants the problem is assessing how these claims relate to any putative activities that are described. Ethnographers deal with these problems with varying degrees of sophistication (for discussion see Nelson, 1994). However, some researchers treat them as inescapable and have turned to some form of discourse analysis instead.

For more detailed discussions of ethnography readers should start with Fielding's (1993) excellent brief introduction and then use Hammersley and Atkinson (1995) as an authoritative and up to date overview. Two of the most comprehensive, although not always most sophisticated, works are Werner and Schoepfle (1987) and Ellen (1984). Both were written by anthropologists, and this shows in their understanding of what is important. Newfield, Sells, Smith, Newfield, and Newfield (1996) provide a useful discussion of ethnography in family therapy research.

3.06.4 DISCOURSE ANALYSIS

Although both grounded theorizing and ethnographic work in clinical areas has increased, the most striking expansion has been in research in discourse analysis (Soyland, 1995). This work is of variable quality and often done by researchers isolated in different subdisciplines; moreover, it displays considerable terminological confusion. For simplicity, discourse analysis is taken as covering a range of work which includes conversation analysis and ethnomethodology (Heritage, 1984; Nofsinger, 1991), some specific traditions of discourse analysis and discursive psychology (Edwards & Potter, 1992a; Potter & Wetherell, 1987), some of the more analytically focused social constructionist work (McNamee & Gergen, 1992), and a range of work influenced by post-structuralism, Continental discourse analysis, and particularly the work of Foucault (Burman, 1995; Madigan, 1992; Miller & Silverman, 1995). In some research these different themes are woven together; elsewhere strong oppositions are marked out.

The impetus for discourse analysis in clinical settings comes from two directions. On the one hand, there are practitioner/researchers who have found ideas from social constructionism, literary theory, and narrative useful (e.g., Anderson & Goolishian, 1988; White & Epston, 1990). On the other, there are academic researchers who have extended analytic and theoretical developments in discourse studies to clinical settings (e.g., Aronsson & Cederborg, 1996; Bergmann, 1992; Buttny, 1996; Edwards, 1995; Lee, 1995). Collections such as Siegfried (1995), Burman, Mitchel, and Salmon (1996), and Morris and Chenail (1995) reflect both types of work, sometimes in rather uneasy combination (see Antaki, 1996).

This tension between an applied and academic focus is closely related to the stance taken on therapy. In much discourse analysis, therapy is the start point for research and the issue is how therapy gets done. For example, Gale's (1991; Gale & Newfield, 1992) intensive study of one of O'Hanlon's therapy sessions considered the various ways in which the goals of solution focused family therapy were realized in the talk between therapist and client. However, some conversation analysts and ethnomethodologists resist assuming that conversational interaction glossed by some parties as therapy (solution focused, Milan School, or whatever) must have special ingredient X—therapy—that is absent in, say, the everyday "troubles talk" done with a friend over the telephone (Jefferson, 1988; Jefferson & Lee, 1992; Schegloff, 1991; Watson, 1995).

This is a significant point for all researchers into therapy and counseling, so it is worth illustrating with an example. In Labov and Fanshel's classic study, the therapy session starts in the following manner:

Rhoda:	I don't (1.0) know, whether (1.5) I-I think I did- the right thing, jistalittle situation came up (4.5) an' I tried to uhm (3.0) well, try to (4.0) use what I- what I've learned here, see if it worked (0.3)
Therapist:	Mhm
Rhoda:	Now, I don't know if I did the right thing. Sunday (1.0) um- my mother went to my sister's again.
Therapist:	Mm-hm
Rhoda:	And she usu'lly goes for about a day or so, like if she leaves on Sunday, she'll come back Tuesday morning. So- it's nothing. But- she lef' Sunday, and she's still not home.
Therapist:	O- oh. (1977, p. 263)

Labov and Fanshel provide many pages of analysis of this sequence. They identify various direct and indirect speech acts and make much of what they call its therapeutic interview style, particularly the vague reference terms at the start: "right thing" and "jistalittle situation." This vagueness can easily be heard as the 19-year-old anorexia sufferer struggling to face up to her relationship with her difficult mother. However, in a reanalysis from a conversation analytic perspective, Levinson (1983) suggests that this sequence is characteristic of mundane news telling sequences in everyday conversation. These typically have four parts: the pre-announcement, the go ahead, the news telling, and the news receipt. For example:

D:	I forgot to to tell you the two best things that happen' to me today.	preannouncement
R:	Oh super = what were they.	go ahead turn
D:	I got a B+ on my math test . . . and I got an athletic award	news telling
R:	Oh excellent.	news receipt

(Levinson, 1983, p. 349—slightly modified)

A particular feature of preannouncements is their vagueness, for their job is to prefigure the story (and thereby check its newsworthiness), not to actually tell it. So, rather than following Labov and Fanshel (1977) in treating this vagueness as specific to a troubled soul dealing with a difficult topic in therapy, Levinson (1983) proposes that it should be understood as a commonplace characteristic of mundane interaction.

This example illustrates a number of features typical of a range of discursive approaches to therapy talk. First, the talk is understood as performing actions; it is not being used as a pathway to cognitive processes (repression, say) or as evidence of what Rhoda's life is like (her difficult mother). Second, the interaction is understood as sequentially organized so any part of the talk relates to what came immediately before and provides an environment for what will immediately follow. The realization of how far interaction gets its sense from its sequential context has critical implications for approaches such as content analysis and grounded theory which involve making categorizations and considering relations between them; for such categorizations tend to cut across precisely the sequential relations that are important for the sense of the turn of talk.

The third feature is that the talk is treated as ordered in its detail not merely in its broad particulars. For example, Levinson (1983) highlights a number of orderly elements in what we might easily mistake for clumsiness in Rhoda's first turn:

> R's first turn is . . . formulated to prefigure (i) the telling of something she did (*I think I did the right thing*), and (ii) the describing of the situation that led to the action (*jistalittle situation came up*). We are therefore warned to expect a story with two components; moreover the point of the story and its relevance to the here and now is also prefigured (*use what I've learned here, see if it worked*). (1983, p. 353)

Even the hesitations and glottal stops in Rhoda's first turn, which seem so redolent of a troubled young person are "typical markings of self-initiated self-repair, which is characteristic of the production of first topics" (Levinson, 1983, p. 353). This emphasis on the significance of detail has an important methodological consequence—if interaction is to be understood properly it must be represented in a way that captures this detail. Hence the use of a transcription scheme that attempts to represent a range of paralinguistic features of talk (stress, intonation) on the page as well as elements of the style of its delivery (pauses, cut-offs).

A fourth feature to note here is the comparative approach that has been taken. Rather than focus on therapy talk alone Levinson is able to support an alternative account of the interaction by drawing on materials, and analysis, taken from mundane conversations. Since the mid 1980s there has been a large amount of work in different institutional settings as well as everyday conversation, and it is now possible to start to show how a news interview, say, differs from the health visitor's talk with an expectant mother, and how that differs in turn from conversation between two friends over the telephone (Drew & Heritage, 1992a).

A fifth and final feature of this example is that it is an analysis of interaction. It is neither an attempt to reduce what is going on to cognitions of the various parties—Rhoda's denial, say, or the therapist's eliciting strategies—nor to transform it into countable behaviors such as verbal reinforcers. This style of discourse work develops a Wittgensteinian notion of cognitive words and phrases as elements in a set of language games for managing issues of blame, accountability, description, and so on (Coulter, 1990; Edwards, 1997; Harré & Gillett, 1994). Such a "discursive psychology" analyzes notions such as attribution and memory in terms of the situated practices through which responsibility is assigned and the business done by constructing particular versions of past events (Edwards & Potter, 1992b, 1993).

3.06.4.1 Questions

Discourse analysis is more directly associated with particular theoretical perspectives—

ethnomethodology, post-structuralism, discursive psychology—than either grounded theory or ethnography. The questions it addresses focus on the practices of interaction in their natural contexts and the sorts of discursive resources that are drawn on those contexts.

Some of the most basic questions concern the standardized sequences of interaction that take place in therapy and counseling (Buttny & Jensen, 1995; Lee, 1995; Peräkylä, 1995; Silverman, 1997b). This is closely related to a concern with the activities that take place. What is the role of the therapist's tokens such as "okay" or "mm hm" (Beach, 1995; Czyzewski, 1995)? How do different styles of questioning perform different tasks (Bergmann, 1992; Peräkylä, 1995; Silverman, 1997b)? What is the role of problem formulations by both therapists and clients, and how are they transformed and negotiated (Buttny, 1996; Buttny & Jensen, 1995; Madill & Barkham, 1997)? For example, in a classic feminist paper Davis (1986) charts the way a woman's struggles with her oppressive social circumstances are transformed into individual psychological problems suitable for individual therapy. While much discourse research is focused on the talk of therapy and counseling itself, studies in other areas show the value of standing back and considering clinical psychology as a set of work practices in themselves, including management of clients in person and as records, conducting assessments, delivering diagnoses, intake and release, stimulating people with profound learning difficulties, case conferences and supervisions, offering advice, and managing resistance (see Drew & Heritage, 1992a). Discourse researchers have also been moving beyond clinical settings to study how people with clinical problems or learning difficulties manage in everyday settings (Brewer & Yearley, 1989; Pollner & Wikler, 1985; Wootton, 1989).

Another set of questions are suggested by the perspective of discursive psychology. For example, Edwards (1997) has studied the rhetorical relationship between problem formulations, descriptions of activities, and issues of blame in counseling. Cheston (1996) has studied the way descriptions of the past in a therapy group of older adults can create a set of social identities for the members. Discursive psychology can provide a new take on emotions, examining how they are constructed and their role in specific practices (Edwards, 1997).

From a more Foucaultian inspired direction, studies may consider the role of particular discourses, or interpretative repertoires in constructing the sense of actions and experiences (Potter & Wetherell, 1987). For example, what are the discursive resources that young women draw on to construct notions of femininity, agency, and body image in the context of eating disorders (Malson & Ussher, 1996; Wetherell, 1996)? What discourses are used to construct different notions of the person, of the family, and of breakdown in therapy (Burman, 1995; Frosh, Burck, Strickland-Clark, & Morgan, 1996; Soal & Kotter, 1996)? This work is often critical of individualistic conceptions of therapy.

Finally, discourse researchers have stood back and taken the administration of psychological research instruments as their topic. The intensive focus of such work can show the way that the sort in idiosyncratic interaction that takes place when filling in questionnaires or producing records can lead to particular outcomes (Antaki & Rapley, 1996; Garfinkel, 1967b; Rapley & Antaki, 1996; Soyland, 1994).

Different styles of discourse work address rather different kinds of questions. However, the conversation analytic work is notable in commonly starting from a set of transcribed materials rather than preformulated research questions, on the grounds that such questions often embody expectations and assumptions which prevent the analyst seeing a range of intricacies in the interaction. Conversation analysis reveals an order to interaction that participants are often unable to formulate in abstract terms.

3.06.4.2 Procedures

The majority of discourse research in the clinical area has worked with records of natural interaction, although a small amount has used open-ended interviews. There is not space here to discuss the role of interviews in discourse analysis or qualitative research generally (see Kvale, 1996; Mischler, 1986; Potter & Mulkay, 1985; Widdicombe & Wooffitt, 1995). For simplicity discourse work will be discussed in terms of seven elements.

3.06.4.2.1 Research materials

Traditionally psychologists have been reluctant to deal with actual interaction, preferring to model it experimentally, or reconstruct it via scales and questionnaires. Part of the reason for this is the prevalent cognitivist assumptions which have directed attention away from interaction itself to focus on generative mechanisms within the person. In contrast, discourse researchers have emphasised the primacy of practices of interaction themselves. The most obvious practice setting for clinical work is the therapy session itself, and this has certainly received the most attention. After all, there is an elegance in studying the "talking cure" using methods designed to acquire an understanding of the nature of talk. However, there is a danger that such an exclusive emphasis underplays mundane aspects of clinical practices: giving advice, offering a diagnosis, the reception of new clients, casual talk to clients' relatives, writing up clinical records, case conferences, clinical training, and assessment.

Notions of sample size do not translate easily from traditional research as the discourse research focus is not so much on individuals as on interactional phenomena of various kinds. Various considerations can come to the fore here, including the type of generalizations that are to be made from the research, the time and resources available, and the nature of the topic being studied. For example, if the topic is the role of "mm hms" in therapy a small number of sessions may generate a large corpus; other phenomena may be much rarer and require large quantities of interaction to develop a useful corpus. For some questions, single cases may be sufficient to underpin a theoretical point or reveal a theoretically significant phenomena.

3.06.4.2.2 Access and ethics

One of the most difficult practical problems in conducting discourse research involves getting access to sometimes sensitive settings in ways which allow for informed consent from all the parties involved. Experience suggests that more often than not it is the health professionals rather than the clients who are resistant to their practices being studied, perhaps because they are sensitive to the difference between the idealized version of practices that was used in training and the apparently more messy procedures in which they actually engage. Sometimes reassurances about these differences can be productive.

Using records of interaction such as these raise particular issues for ensuring anonymity. This is relatively manageable with transcripts where names and places can be changed. It is harder for audio tape and harder still with video. However, technical advances in the use of digitized video allow for disguising of identity with relatively little loss of vocal information.

3.06.4.2.3 Audio and video recording

There is a range of practical concerns in recording natural interaction, some of them pulling in different directions. An immediate issue is whether to use audio or video recording. On the one hand, video provides helpful information about nonverbal activities that may be missed from the tape, and good quality equipment is now compact and cheap. On the other hand, video can be more intrusive, particularly where the recording is being done by one of the participants (a counselor, say), and may be hard to position so it captures gestures and expressions from all parties to an interaction. Video poses a range of practical and theoretical problems with respect to the transcription of nonvocal activity which can be both time consuming and create transcript that is difficult to understand. Moreover, there is now a large body of studies that shows high quality analysis can, in many cases, be performed with an audio tape alone. One manageable solution is to use video if doing so does not disrupt the interaction, and then to transcribe the audio and work with a combination of video tape and audio transcript. Whether audio or video is chosen, the quality (clear audibility and visibility) is probably the single most consequential feature of the recording for the later research.

Another difficulty is how far the recording of interaction affects its nature. This is a subtle issue. On the one hand, there are a range of ways of minimizing such influences including acclimatizing participants and giving clear descriptions of the role of the research. On the other, experience has shown that recording has little influence on many, perhaps most, of the activities in which the discourse researcher is interested. Indeed, in some clinical settings recordings may be made as a matter of course for purposes of therapy and training, and so no new disruption is involved.

3.06.4.2.4 Transcription

Producing a high-quality transcript is a crucial prerequisite for discourse research. A transcript is not a neutral, simple rendition of the words on a tape (Ochs, 1979). Different transcription systems emphasize different features of interaction. The best system for most work of this kind was developed by the conversation analyst Gail Jefferson using symbols that convey features of vocal delivery that have been shown to be interactionally important to participants (Jefferson, 1985). At the same time the system is designed to use characters and symbols easily available on wordprocessors making it reasonably easy to learn and interpret. The basic system is summarized in Table 3. For fuller descriptions of using the system see Button and Lee, (1987), Ochs, Schegloff, and Thompson (1996), and Psathas and Anderson (1990).

Producing high quality transcript is very demanding and time consuming. It is hard to give a standard figure for how long it takes

Table 3 Brief transcription notation.

Um::	colons represent lengthening of the preceding sound; the more colons, the greater the lengthening.
I've-	a hyphen represents the cut-off of the preceding sound, often by a stop.
↑Already	up and down arrows represent sharp upward and downward pitch shifts in the following sounds. Underlining represents stress, usually by volume; the more underlining the greater the stress.
settled in his = Mm = own mind.	the equals signs join talk that is continuous although separated across different lines of transcript.
hhh hh .hh P(h)ut	'h' represents aspiration, sometimes simply hearable breathing, sometimes laughter, etc.; when preceded by a superimposed dot, it marks in-breath; in parenthesis inside a word it represents laugh infiltration.
hhh[hh .hh] [I just]	left brackets represent point of overlap onset; right brackets represent point of overlap resolution.
.,?	punctuation marks intonation, not grammar; period, comma and 'question mark' indicate downward, 'continuative', and upward contours respectively.
( )	single parentheses mark problematic or uncertain hearings; two parentheses separated by an oblique represent alternative hearings.
(0.2)(.)	numbers in parentheses represent silence in tenths of a second; a dot in parentheses represents a micro-pause, less than two tenths of a second.
°mm hmm°	the degree signs enclose significantly lowered volume.

Source: Modified from Schegloff (1997, pp. 184–185).

because much depends on the quality of the recording (fuzzy, quiet tapes can quadruple the time needed) and the type of interaction (an individual therapy session presents much less of a challenge than a lively case conference with a lot of overlapping talk and extraneous noise); nevertheless, a ratio of one hour of tape to twenty hours of transcription time is not unreasonable. However, this time should not be thought of as dead time before the analysis proper. Often some of the most revealing analytic insights come during transcription because a profound engagement with the material is needed to produce good transcript—it is generally useful to make analytic notes in parallel to the actual transcription.

3.06.4.2.5 Coding

In discourse research the principle task of coding is to make the task of analysis more straightforward by sifting relevant materials from a large body of transcript. In this it differs from both grounded theory and traditional content analysis where coding is a more intrinsic part of the analysis. Typically coding will involve sifting through materials for instances of a phenomenon of interest and copying them into an archive. This coding will often be accompanied by preliminary notes as to their nature and interest. At this stage selection is inclusive—it is better to include material that can turn out to be irrelevant at a later stage than exclude it for ill-formulated reasons early on. Coding is a cyclical process. Full analysis of a corpus of materials can often take the researcher back to the originals as a better understanding of the phenomenon reveals new examples. Often initially disparate topics merge together in the course of analysis while topics which seemed unitary can be separated.

3.06.4.2.6 Analysis

There is no single recipe for analyzing discourse. Nevertheless, there are five considerations which are commonly important in analysis. First, the researcher can use variation in and between participants' discourse as an analytic lever. The significance of variation is that it can be used for identifying and explicating the activities that are being performed by talk and texts. This is because the discourse is constructed in the specific ways that it is precisely to perform these actions; a description of jealousy in couple counseling can be assembled very differently when excusing or criticizing certain actions (Edwards, 1995). The researcher will benefit from attending to variations in the discourse of single individuals, between different individuals, and between what is said and what might have been said.

Second, discourse researchers have found it highly productive to attend to the detail of discourse. Conversation analysts such as Sacks (1992) have shown that the details in discourse—the hesitations, lexical choice, repair, and so on—are commonly part of the performance of some act or are consequential in some way for the outcome of the interaction. Attending to the detail of interaction, particularly in transcript, is one of the most difficult things for psychologists who are used to reading through the apparently messy detail for the gist of what is going on. Developing analytic skills involves a discipline of close reading.

Third, analysis often benefits from attending to the rhetorical organization of discourse. This involves inspecting discourse both for the way it is organized to make argumentative cases and for the way it is designed to undermine alternative cases (Billig, 1996). A rhetorical orientation refocuses the analyst's attention away from questions about how a version—description of a psychological disorder, say—relates to some putative reality and focuses it on how it relates to competing alternatives.

Concern with rhetoric is closely linked to a fourth analytic concern with accountability. That is, displaying one's activities as rational, sensible, and justifiable. Ethnomethodologists have argued that accountability is an essential and pervasive character of the design and understanding of human conduct generally (Garfinkel, 1967c; Heritage, 1984). Again an attention to the way actions are made accountable is an aid for understanding precisely what those actions are.

A fifth and final analytic consideration is of a slightly different order. It is an emphasis on the virtue of building on prior analytic studies. In particular, researchers into interaction in an institutional setting such as a family therapy setting will almost certainly benefit from a familiarity with research on mundane talk as well as an understanding of how the patterning of turn taking and activities change in different institutional settings.

The best way to think of these five considerations is not as specific rules for research but as elements in an analytic mentality that the researcher will develop as they become more and more skilled. It does not matter that they are not spelled out in studies because they are separate from the procedures for validating discourse analytic claims.

3.06.4.2.7 Validity

Discourse researchers typically draw on some combination of four considerations to justify the validity of analytic claims. First, they make use of participants' own understandings as they are displayed in interaction. One of the features of a conversation is that any turn of talk is oriented to what came before and what comes next, and that orientation typically displays the sense that the participant makes of the prior turn. Thus, at its simplest, when someone provides an answer they thereby display the prior turn as a question and so on. Close attention to this turn-by-turn display of understanding provides one important check on analytic interpretations (see Heritage, 1988).

Second, researchers may find (seemingly) deviant cases most useful in assessing the adequacy of a claim. Deviant cases may generate problems for a claimed generalization, and lead the researcher to abandon it; but they may also display in their detailed organization precisely the reason why a standard pattern should take the form that it does.

Third, a study may be assessed in part by how far it is coherent with previous discourse studies. A study that builds coherently on past research is more plausible than one that is more anomalous.

Fourth, and most important, are readers' evaluations. One of the distinctive features of discourse research is its presentation of rich and extended materials in a way that allows the reader to make their own judgements about interpretations that are placed along side of them. This form of validation contrasts with much grounded theory and ethnography where interpretations often have to be taken on trust; it also contrasts with much traditional experimental and content analytic work where it is rare for "raw" data to be included or more than one or two illustrative codings to be reproduced.

Whether they appear singly or together in a discourse study none of these procedures guarantee the validity of an analysis. However, as the sociology of science work reviewed earlier shows, there are no such guarantees in science.

3.06.4.3 Example: Peräkylä (1995)

Given the wide variety of discourse studies with different questions and styles of analysis it is not easy to chose a single representative study. The one selected is Peräkylä's (1995) investigation of AIDS counseling because it is a major integrative study that addresses a related set of questions about interaction, counseling, and family therapy from a rigorous conversation analytic perspective and illustrates the potential of discourse work on clinical topics. It draws heavily on the perspective on institutional talk surveyed by Drew and Heritage (1992b) and is worth reading in conjunction with Silverman's (1997b) related study of HIV+ counseling which focuses more on advice giving.

Peräkylä focused on 32 counseling sessions conducted with HIV+ hemophilic mainly gay identified men and their partners at a major London hospital. The sessions were videotaped and transcribed using the Jeffersonian system. A wider archive of recordings (450 hours) was drawn on to provide further examples of phenomena of interest but not otherwise transcribed. The counselors characterized their practices in terms of Milan School Family Systems Theory and, although this is not the startpoint of Peräkylä's study, he was able to explicate some of the characteristics of such counseling.

Part of the study is concerned with identifying the standard turn-taking organization of the counseling. Stated baldly it is that (i) counselors ask questions; (ii) clients answer; (iii) counselors comment, advise, or ask further questions. When laid out in this manner the organization may not seem much of a discovery. However, the power of the study is showing how this organization is achieved in the interaction and how it can be used to address painful and delicate topics such as sexual behavior, illness, and death.

Peräkylä goes on to examine various practices that are characteristic of family systems theory such as "circular questioning," where the counselor initially questions the client's partner or a family member about the client's feelings, and "live open supervision," where a supervisor may offer questions to the counselor that are, in turn, addressed to the client. The study also identifies some of the strategies by which counselors can address "dreaded issues" in a manageable way. Take "circular questioning," for example. In mundane interaction providing your partial experience of some event or experience is a commonplace way of "fishing" for a more authoritative version (Pomerantz, 1980). For example:

A: Yer line's been busy.
B: Yeuh my fu (hh)- .hh my father's
wife called me

In a similar way, the use of questioning where a client's partner, say, offers their understanding of an experience "can create a situation where the clients, in an unacknowledged but most powerful way, elicit one another's descriptions of their inner experiences" (Peräkylä, 1995, p. 110). In the following extract the client is called Edward; his partner and the counselor are also present.

Counselor: What are some of things that you
think E:dward might have to
do. = He says he doesn't know
where to go from here maybe: and
awaiting results and things.
(0.6)
Counselor: What d'you think's worrying him.
(0.4)
Partner: Uh::m hhhhhh I think it's just fear
of the unknow:n.
Client: Mm[:
Counselor: [Oka:y.
Partner: [At- at the present ti:me. (0.2)
Uh:m (.) once: he's (0.5) got a better
understanding of (0.2) what could
happen
Counselor: Mm:
Partner: uh:m how .hh this will progre:ss
then: I think (.) things will be a
little more [settled in his =
Counselor: [Mm
Partner: = own mi:nd.
Counselor: Mm:
(.)
Client: Mm[:
Counselor: [Edward (.) from what you
know::
((sequence continues with Edward
responding to a direct question
with a long and detailed narrative
about his fears))
(Peräkylä, 1995, p. 110)

Peräkylä emphasizes the way that the client's talk about his fears is elicited, in part, through the counsellor asking the partner for his own view of those fears. The point is not that the client is forced to reveal his experiences, rather it is that the prior revelation of his partner's partial view produces an environment where such a revelation is expected and nonrevelation will itself be a delicate and accountable matter. In effect, what Peräkylä is documenting here are the conversational mechanisms which family therapists characterize as using circular questioning to overcome clients' resistance.

3.06.4.4 Virtues and Limitations

Given the variety of styles of work done under the rubric of discourse analysis it is difficult to give an overall summary of virtues and limitations. However, the virtue of a range of studies in the conversation and discourse analytic tradition is that they offer, arguably for the first time in psychology, a rigorous way of directly studying human social practices. For example, the Peräkylä study discussed above is notable in studying actual HIV + counseling in all its detail. It is not counseling as recollected by participants while filling in rating scales or questionnaires; it is not an experimental simulation of counseling; it does not depend on *post hoc* ethnographic reconstructions of events; nor are the activities immediately transformed into broad coding categories or used as a mere shortcut to underlying cognitions.

A corollary of this emphasis on working with tapes and transcripts of interaction is that these are used in research papers to allow readers to evaluate the adequacy of interpretations in a way that is rare in other styles of research.

Studies in this tradition have started to reveal an organization of interaction and its local management that has been largely missed from traditional psychological work from a range of perspectives. Such studies offer new conceptions of what is important in clinical practice and may be particularly valuable in clinical training which has often been conducted with idealized or at least cleaned up examples of practice.

Discourse research is demanding and requires a considerable investment of the researcher's time to produce satisfactory results. It does not fit neatly into routines that can be done by research assistants. Indeed, even transcription, which may seem to be the most mechanical element in the research, requires considerable skill and benefits from the involvement of the primary researchers. Analysis also requires considerable craft skills which can take time to learn.

With its focus on interaction, this would not necessarily be the perspective of choice for researchers with a more traditional cognitive or behavioral focus, although it has important implications for both of these. Some have claimed that it places too much emphasis on verbal interaction at the expense of nonverbal elements, and broader issues of embodiment. Others have claimed that it places too much emphasis on the importance of local contexts of interaction rather than on broader issues such as gender or social class. For some contrasting and strongly expressed claims about the role of discourse analysis in the cognitive psychology of memory, see papers in Conway (1992).

An accessible general introduction to various practical aspects of doing discourse analysis is provided in Potter and Wetherell (1987; see also Potter, 1996b, 1997). Potter and Wetherell (1995) discuss the analysis of broader content units such as interpretative repertoires, while Potter and Wetherell (1994) and Wooffitt (1993) discuss the analysis of how accounts are constructed. For work in the distinctive conversation analytic tradition Drew (1995) and Heritage (1995) provide clear overviews and Heath and Luff (1993) discuss analysis which incorporates video material; Gale (1996) explores the use of conversation analysis in family therapy research.

3.06.5 FUTURE DIRECTIONS

The pace of change in qualitative research in clinical settings is currently breathtaking, and it is not easy to make confident predictions. However, it is perhaps useful to speculate on how things might develop over the next few years. The first prediction is that the growth in the sheer quantity of qualitative research will continue for some time. There is so much new territory, and so many possibilities have been opened up by new theoretical and analytic developments, that they are bound to be explored.

The second prediction is that research on therapy and counseling talk will provide a particular initial focus because it is here that discourse analytic approaches can clearly provide new insights and possibly start to provide technical analytically grounded specifications of the interactional nature of different therapies in practice, as well as differences in interactional style between therapists. There may well be conflicts here between the ideological goals of constructionist therapists and the research goals of discourse analysts.

The third prediction is that the growth of qualitative work will encourage more researchers to attempt integrations of qualitative and quantitative research strategies. There will be attempts to supplement traditional outcomes research with studies of elements of treatment which are not easily amenable to quantification. Here the theoretical neutrality of grounded theory (ironically) is likely to make for easier integration than the more theoretically developed discourse perspectives. The sheer difficulty of blending qualitative and quantitative work should not be underestimated—research that has attempted this has often found severe problems (see Mason, 1994, for a discussion).

The final prediction is that there will be an increased focus on clinical work practices embodied within settings such as clinics and networks of professional and lay relationships. Here the richness of ethnographic work will be drawn on, but increasingly the conversation analytic discipline of working with video and transcript will replace field notes and recollections. Such work will have the effect of respecifying some of the basic problems of clinical research. Its broader significance, however, may depend on the course of wider debates in Psychology over the development and success of the cognitive paradigm and whether it will have a discursive and interaction based successor.

ACKNOWLEDGMENTS

I would like to thank Alan Bryman, Karen Henwood, Alexa Hepburn, Celia Kitzinger, and Denis Salter for making helpful comments on an earlier draft of this chapter.

3.07.1 INTRODUCTION

Most domains of psychology have documented the importance of personality traits to adaptive and maladaptive functioning, including the fields of behavioral medicine (Adler & Matthews, 1994), psychopathology (Watson, Clark, & Harkness, 1994; Widiger & Costa, 1994), and industrial-organizational psychology (Hogan, Curphy, & Hogan, 1994). The assessment of personality is perhaps fundamental to virtually all fields of applied psychology. However, there are as many as 4500 different personality traits, or at least 4500 different trait terms within the English language (Goldberg, 1990) and there might be almost as many personality assessment instruments. There are instruments for the assessment of individual traits (e.g., tender-mindedness), for collections of traits (e.g., the domain of agreeableness, which includes tender-mindedness, trust, straightforwardness, altruism, compliance, and modesty), for constellations of traits (e.g., the personality syndrome of psychopathy, which includes such traits as arrogance, superficial charm, impulsivity, callousness, arrogance, deception, irresponsibility, and low empathy), and for traits identified by theorists for which there might not yet be a specific term within the language (e.g., extratensive experience balance; Exner, 1993).

There are also different methods for the assessment of personality traits. The primary methods used in personality research are self-report inventories, semistructured interviews, and projective techniques. Self-report inventories consist of written statements or questions, to which a person responds in terms of a specified set of options (e.g., true vs. false or agree vs. disagree along a five-point scale). Semistructured interviews consist of a specified set of verbally administered questions, accompanied by instructions (or at least guidelines) for follow-up questions and for the interpretation and scoring of responses. Projective techniques consist of relatively ambiguous stimuli or prompts, the possible responses to which are largely open-ended, accompanied by instructions (or at least guidelines) for their scoring or interpretation. The distinctions among these three methods, however, is somewhat fluid. A self-report inventory is equivalent to a fully structured, self-administered interview; semistructured interviews are essentially verbally administered self-report inventories that include at least some open-ended questions; and fully structured interviews are essentially verbally administered self-report inventories.

Each of the methods will be considered below, including a discussion of issues relevant to or problematic for that respective method. However, the issues discussed for one method of assessment will apply to another. Illustrative instruments for each method are also presented.

3.07.2 SELF-REPORT INVENTORIES

The single most popular method for the assessment of personality by researchers of normal personality functioning is a self-report inventory (SRI). The advantages of SRIs, relative to semistructured interviews and projective techniques, are perhaps self-evident. They are substantially less expensive and time-consuming to administer. Data on hundreds of persons can be obtained, scored, and analyzed at relatively little cost to the researcher. Their inexpensive nature allows collection of vast amounts of normative data that are unavailable for most semistructured interviews and projective techniques. These normative data in turn facilitate substantially their validation, as well as their interpretation by and utility to researchers and clinicians.

The high degree of structure of SRIs has also contributed to much better intersite reliability than is typically obtained by semistructured interviews or projective techniques. The findings of SRIs are very sensitive to the anxious, depressed, or angry mood states of respondents, contributing at times to poor test–retest reliability (discussed further below). However, the correlation between two SRIs is much more likely to be consistent across time and across research sites than the correlation between two semistructured interviews or two projective techniques. SRIs might be more susceptible to mood state distortions than semistructured interviews, but this susceptibility may itself be observed more reliably across different studies than the lack of susceptibility of semistructured interviews.

The specific and explicit nature of SRIs has also been very useful in researching and understanding the source and nature of subjects' responses. Much more is known about the effects of different item formats, length of scales, demographic variables, base rates, response sets, and other moderating variables from the results of SRIs than from semistructured interviews or projective techniques. Five issues to be discussed below are (i) item analyses; (ii) gender, ethnic, and cultural differences; (iii) individual differences; (iv) response distortion; and (v) automated assessments.

3.07.2.1 Item Analyses

There are a variety of methods for constructing, selecting, and evaluating the items to be included within an SRI (Clark & Watson, 1995). However, it is useful to highlight a few points within this chapter as such analyses are of direct importance to personality assessment research.

An obvious method for item construction, often termed the rational approach, is to construct items that describe explicitly the trait being assessed. For example, the most frequently used SRI in clinical research for the assessment of personality disorders is the Personality Diagnostic Questionnaire-4 (PDQ-4; Hyler, 1994). Its items were written to inquire explicitly with respect to each of the features of the 10 personality disorders included in the American Psychiatric Association's (APA) *Diagnostic and statistical manual of mental disorders* (*DSM-IV*; APA, 1994). For example, the dependent personality criterion, "has difficulty expressing disagreement with others because of fear of loss of support or approval" (APA, 1994, p. 668) is assessed by the PDQ-4 item, "I fear losing the support of others if I disagree with them" (Hyler, 1994, p. 4).

The content validity of an SRI is problematic to the extent that any facets of the trait being assessed are not included or are inadequately represented, items representing other traits are included, or the set provides a disproportionately greater representation of one facet of the trait relative to another (Haynes, Richard, & Kubany, 1995). "The exact phrasing of items can exert a profound influence on the construct that is actually measured" (Clark & Watson, 1995, p. 7) yet the content of items often receives little consideration in personality assessment research. Widiger, Williams, Spitzer, and Frances (1985) concluded from a systematic content analysis of the Millon Clinical Multiaxial Inventory (MCMI; Millon, 1983) that the MCMI failed to represent adequately many significant features of the antisocial personality disorder.

> Many of the [personality] traits are not sampled at all (e.g., inability to sustain consistent work behavior, lack of ability to function as a responsible parent, inability to maintain an enduring attachment to a sexual partner, failure to plan ahead or impulsivity, and disregard for the truth), including an essential requirement of the *DSM-III* antisocial criteria to exhibit significant delinquent behavior prior to the age of 15. (Widiger et al., 1985, p. 375)

Many MCMI-III items are written in part to represent an alternative theoretical formulation for the *DSM-IV* personality syndromes (Millon et al., 1996).

High content validity, however, will not ensure a valid assessment of a respective personality trait. Although many of the PDQ-4 dependency items do appear to represent adequately their respective diagnostic criteria, it is difficult to anticipate how an item will actually perform when administered to persons with varying degrees of dependency and to persons with varying degrees of other personality traits, syndromes, or demographic characteristics. Most authors of SRIs also consider the findings of internal consistency analyses (Smith & McCarthy, 1995). "Currently, the single most widely used method for item selection in scale development is some form of internal consistency analysis" (Clark & Watson, 1995, p. 313).

Presumably, an item should correlate more highly with other items from the same scale (e.g., dependent personality traits) than items from another scale (e.g., borderline personality traits), consistent with the basic principles of convergent and discriminant validity. However, these assumptions hold only for personality syndromes that are homogeneous in content and that are distinct from other syndromes, neither of which may be true for syndromes that involve overlapping constellations of personality traits (Pilkonis, 1997; Shea, 1995). Confining a scale to items that correlate highly with one another can result in an overly narrow assessment of a construct, and deleting items that correlate highly with other scales can result in false distinctions and a distorted representation of the trait being assessed (Clark & Watson, 1995; Smith & McCarthy, 1995). For example, the APA (1994) criteria set for the assessment of antisocial personality disorder does not include such items as lacks empathy and arrogant self-appraisal that are included in alternative criteria sets for this personality syndrome (Hare, 1991) in part because these items are already contained within the *DSM-IV* criteria set for the narcissistic personality disorder. Their inclusion within the criteria set for antisocial personality disorder would complicate the differentiation of the antisocial and narcissistic personality syndromes (Gunderson, 1992), but the failure to include these items may also provide an inadequate description and assessment of antisocial (psychopathic) personality traits (Hare, Hart, & Harpur, 1991).

Overlapping scales, on the other hand, have their own problems, particularly if they are to be used to test hypotheses regarding the relationships among or differences between the traits and syndromes being assessed (Helmes & Reddon, 1993). For example, the MCMI-III personality scales overlap substantially (Millon, Millon, & Davis, 1994). Scale overlap was in part a pragmatic necessity of assessing 14 personality disorders and 10 clinical syndromes with no more than 175 items. However, this overlap was also intentional to ensure that the scales be consistent with the overlap of the personality constructs being assessed. "Multiple keying or item overlapping for the MCMI inventories was designed to fit its theory's polythetic structure, and the scales constructed to represent it" (Millon, 1987, p. 130). However, the MCMI-III cannot then be used to assess the validity of this polythetic structure, or to test hypotheses concerning the covariation, differentiation, or relationship among the personality constructs, as the findings will be compelled by the scale overlap (Helmes & Reddon, 1993). For example, the MCMI-III provides little possibility for researchers to fail to confirm a close relationship between, or comparable findings for, sadistic and antisocial personality traits, given that eight of the 17 antisocial items (47%) are shared with the sadistic scale. The same point can be made for studies using the Minnesota Multiphasic Personality Inventory (MMPI-2) antisociality and cynicism scales, as they share approximately a third of their items (Helmes & Reddon, 1993). It was for this reason that Morey, Waugh, and Blashfield (1985) developed both overlapping and nonoverlapping MMPI personality disorder scales.

Scale homogeneity and interscale distinctiveness are usually emphasized in SRIs constructed through factor analyses (Clark & Watson, 1995). For example, in the construction of the NEO Personality Inventory-Revised (NEO-PI-R), Costa and McCrae (1992)

> adopted factor analysis as the basis for item selection because it identifies clusters of items that covary with each other but which are relatively independent of other item clusters—in other words, items that show convergent validity with respect to other items in the cluster and divergent validity with respect to other items [outside the cluster]. (p. 40)

Reliance upon factor analysis for scale construction has received some criticism (Block, 1995; Millon et al., 1996) and there are, indeed, instances in which factor analyses have been conducted with little appreciation of the limitations of the approach (Floyd & Widaman, 1995), but this is perhaps no different than for any other statistical technique. Factor analysis remains a powerful tool for identifying underlying, latent constructs, for data reduction, and for the validation of an hypothesized dimensional structure (Smith & McCarthy, 1995; Watson et al., 1994). In any case, the construction of the NEO-PI-R through factor analysis was consistent with the theoretical model for the personality traits being assessed (Clark & Watson, 1995; Costa & McCrae, 1992; Goldberg, 1990). Additional illustrations of theoretically driven factor analytic scale constructions are provided by the Dimensional Assessment of Personality Pathology—Basic Questionnaire (DAPP-BQ; Livesley & Jackson, in press), the Schedule for Nonadaptive and Adaptive Personality (SNAP; Clark, 1993), the Interpersonal Adjective Scales (IAS; Wiggins & Trobst, 1997), the Multidimensional Personality Questionnaire (MPQ; Tellegen & Waller, in press), and the Temperament and Character Inventory (TCI; Cloninger & Svrakic, 1994).

The most informative item analyses will be correlations with external validators of the personality traits, including the ability of items to identify persons with the trait in question, correlations with hypothesized indicators of the trait, and an absence of correlations with variables that are theoretically unrelated to the trait (Smith & McCarthy, 1995). These data typically are discussed under a general heading of construct validity, including data concerning items' concurrent, postdictive, predictive, convergent, and discriminant validity (Ozer & Reise, 1994). Illustrative studies with SRIs include Ben-Porath, McCully, and Almagor (1993), Clark, Livesley, Schroeder, and Irish (1996), Lilienfeld and Andrews (1996), Robins and John (1997), and Trull, Useda, Coasta, and McCrae (1995).

The MMPI-2 clinical scales exemplify the purely empirical approach to scale construction. "The original MMPI (Hathaway & McKinley, 1940) was launched with the view that the content of the items was relatively unimportant and what actually mattered was whether the item was endorsed by a particular clinical group" (Butcher, 1995, p. 302). This allowed the test to be "free from the restriction that the subject must be able to describe his own behavior accurately" (Meehl, 1945, p. 297). For example, one of the items on the MMPI hysteria scale was "I enjoy detective or mystery stories" (keyed false; Hathaway & McKinley, 1982).

Indicating that one does not enjoy detective or mystery stories does not appear to have any obvious (or perhaps even meaningful) relationship to the presence of the mental disorder of hysteria, but answering false did correlate significantly with the occurrence of this disorder. "The literal content of the stimulus (the item) is entirely unimportant, and even irrelevant and potentially misleading. Sophisticated psychometric use of test items dictates that the test interpreter ignore item content altogether lest he or she be misled" (Ben-Porath, 1994, p. 364). Limitations to this approach, however, are suggested below.

A sophisticated approach to item analysis is item response theory (IRT; Hambleton, Swaminathan, & Rogers, 1991). Its most unique datum is the probability of a response to a particular item given a particular level of the personality trait being assessed. IRT analyses demonstrate graphically how items can vary in their discriminative ability at different levels of the trait being assessed (assuming that the anchoring items are not themselves systematically biased). It is not the case that all items perform equally well, nor does any particular item perform equally well at all levels of the trait. It may be the case that none of the items on a scale provide any discrimination at particular levels of a trait, or that the scale is predominated by items that discriminate at high rather than moderate or low levels of the trait. For example, it is possible that the MMPI-2 items to assess the personality domain of neuroticism are weighted toward a discrimination of high levels of neuroticism, providing very little discrimination at low levels. IRT analyses might allow researchers to maximize the sensitivity of a test to a particular population (e.g., inpatient hospital vs. prison setting) by deleting items that work poorly within certain settings (Embretson, 1996). IRT analyses have been used widely with tests of abilities and skills, and are now being applied to measures of personality (Ozer & Reise, 1994). Illustrative applications include analyses of items from the MPQ (Tellegen & Waller, in press) by Reise and Waller (1993), items from a measure of alexithymia by Hendryx, Haviland, Gibbons, and Clark (1992) and items from a psychopathy semistructured interview by Cooke and Michie (1997).

3.07.2.2 Gender, Ethnic, and Cultural Differences

Differences among gender, ethnic, cultural, and other demographic populations with respect to personality traits are often socially sensitive, politically controversial, and difficult to explain (Eagly, 1995). There is substantial SRI research to indicate differences, on average, between males and females for a wide variety of personality traits, as assessed by research with SRIs (Sackett & Wilk, 1994). For example, males obtain higher scores on measures of assertiveness and self-esteem; whereas females obtain higher scores on measures of anxiousness, trust, gregariousness, and tender-mindedness (Feingold, 1994).

Separate norms therefore have been developed for the interpretation of most SRI personality scales (e.g., Costa & McCrae, 1992; Graham, 1993; Millon et al., 1994). However, the rationale for providing different norms for each sex (gender) is unclear. Sackett and Wilk (1994) "searched test manuals, handbooks, and the like for a discussion of the rationale for the practice. We typically found none" (p. 944). They indicated, with some surprise, that the provision of separate norms for males and females "does not seem to have been viewed as at all controversial" (Sackett & Wilk, 1994, p. 944). If the SRI is indicating an actual difference between males and females (Feingold, 1994) it is unclear why this difference showed then be eliminated or diminished in SRI assessments of males and females (Kehoe & Tenopyr, 1994; Sackett & Wilk, 1994).

For example, males and females with the same raw score on the psychopathic deviate scale of the MMPI-2 will be given different final scores due to the use of different norms. Different raw scores for males and females can then result in the same final score (Graham, 1993). The extent of psychopathy in females is then relative to other females; it is not a measure of the actual (absolute) extent to which they are psychopathic. A male who has more traits (or symptoms) of psychopathy could be described by the MMPI-2 as being less psychopathic than a female with the same number of traits. The separate norms provided for males and females on SRIs are never so substantial as to eliminate entirely the differences between the sexes, but the rationale for reducing or minimizing any differences is unclear.

The provision of separate norms for males and females by SRIs is inconsistent with other domains of assessment, including most semistructured interview and projective assessments of personality variables. For example, the same threshold is used for males and females by the most commonly used semistructured interview for the assessment of psychopathy, the (revised) Psychopathy Checklist (Hare, 1991). Separate norms are not provided for females and males in the assessment of intelligence, nor are they provided for different cultural and ethnic groups in the assessment of personality. Although statistically significant differences have also been obtained across ethnic and cultural groups for SRI personality measures, "none of the major personality measures ... offered norm scoring based on race or ethnicity either as a routine aspect of the scoring system or as a scoring option" (Sackett & Wilk, 1994, p. 947). It is unclear whether separate norms should be provided for ethnic groups, but it does appear to be inconsistent to provide separate norms for gender and not for ethnicity.

Separate norms would be appropriate if there is reason to believe that the SRI items are biased against a particular gender, ethnic, or cultural group. "Bias is the extent to which measured group differences are invalid ... Group differences are invalid to the extent that the constructs that distinguish between groups are different from the constructs the measures were intended to represent" (Kehoe & Tenopyr, 1994, p. 294). Consider, for example, the MMPI item cited earlier, "I enjoy detective or mystery stories" (Hathway & McKinley, 1982, p. 3). The MMPI reliance upon a blind empiricism for item selection can be problematic if the basis for the item endorsement is for reasons other than, or in addition to, the presence of the construct being assessed. Lindsay and Widiger (1995) suggested that this item might have been correlated with hysteria because hysteria was itself correlated with female gender. Significantly more females than males are diagnosed with hysteria and significantly more females than males respond negatively to an interest in detective or mystery stories; therefore, the item may have correlated with hysteria because it was identifying the presence of females rather than the presence of hysteria. In addition,

> because such an item concerns normal behavior that occurs more often in one sex than in the other, we would consider it to be sex biased because its errors in prediction (false positives) will occur more often in one sex than in the other. (Lindsay & Widiger, 1995, p. 2)

One would never consider including as one of the *DSM-IV* diagnostic criteria for histrionic personality disorder, "I have often enjoyed reading Cosmopolitan and Ms. Magazine" but many such items are included in SRIs to diagnose the presence of a personality disorder. For example, responding false to the item "in the past, I've gotten involved sexually with many people who didn't matter much to me," is used for the assessment of a dependent personality disorder on the MCMI-II (Millon, 1987, p. 190). Not getting involved sexually with many people who do not matter much is hardly an indication of a dependent personality disorder (or of any dysfunction), yet it is used to diagnose the presence of this personality disorder.

There are also data to suggest that the same items on an SRI may have a different meaning to persons of different ethnic, cultural, or gender groups (Okazaki & Sue, 1995), although the magnitude, consistency, and significance of these differences has been questioned (Ozer & Reise, 1994; Timbrook & Graham, 1994). Applications of IRT analyses to the assessment of bias would be useful (Kehoe & Tenopyr, 1994). For example, Santor, Ramsay, and Zuroff (1994) examined whether men and women at equal levels of depression respond differentially to individual items. They reported no significant differences for most items, but bias was suggested for a few, including a body-image dissatisfaction item. Females were more likely to endorse body-image dissatisfaction than males even when they were at the same level of depression as males, suggesting that the endorsement of the item by women (relative to men) reflected their gender independently of their level of depression.

3.07.2.3 Individual Differences

The provision of any set of norms may itself be questioned. Personality description with SRIs traditionally has been provided in reference to individual differences. "Raw scores on personality inventories are usually meaningless—responses take on meaning only when they are compared to the responses of others" (Costa & McCrae, 1992, p. 13). However, this individual differences approach can itself be problematic. "The individual differences research paradigm, which has thoroughly dominated empirical personality research throughout the present century, is fundamentally inadequate for the purposes of a science of personality" (Lamiell, 1981, p. 36). Lamiell's scathing critique of individual differences research raised many important and compelling concerns. For example, he noted how the test–retest reliability of a personality scale typically is interpreted as indicating the extent to which the expression of a trait is stable in persons across time, but most analyses in fact indicate the extent to which persons maintain their relative position on a scale over time. The test–retest reliability of relative position may itself correlate highly with the test–retest reliability of the magnitude within each person, but it need not. For example, the reliability of a measure of height, assessed across 100 persons using a product-moment correlation, would suggest substantial stability between the ages of eight and 15, despite the fact that each person's actual height would have changed substantially during this time. Height is not at all consistent or stable across childhood, yet a measure of stability in height would be very high if the relative height among the persons changed very little. This confusion, however, would be addressed by alternative reliability statistics (e.g., an intraclass correlation coefficient).

Interpreting personality test scores relative to a particular population is not necessarily problematic as long as the existence of these norms and their implications for test interpretation are understood adequately. For example, a score on an MMPI-2 social introversion scale does not indicate how introverted a person is, but how much more (or less) introverted the person is relative to a particular normative group. The MMPI-2 social introversion scale does not indicate the extent to which an Asian-American male is socially introverted, it indicates how more (or less) introverted he is relative to a sample of 1138 American males who provided the normative data, only 1% of whom were Asian-American (Graham, 1993).

Nevertheless, researchers and clinicians will at times refer to SRI results as if they are providing an absolute measure of a personality trait. For example, researchers and clinicians will describe a person as having high self-esteem, low self-monitoring, or high dependency, when in fact the person is simply higher or lower than a particular comparison group. It is common in personality research to construct groups of subjects on the basis of median splits on SRI scores for such traits as self-esteem, self-monitoring, dependency, autonomy, or some other personality construct. Baumeister, Tice, and Hutton (1989) searched the literature for all studies concerning self-esteem. "Most often ...

high and low self-esteem groups are created by performing a median split on the self-esteem scores across the sample" (p. 556). Persons above the median are identified as having "high self-esteem" whereas persons below the median are identified as having "low self-esteem." However, interpreting SRI data in this manner is inaccurate and potentially misleading. Persons below a median would indeed have less self-esteem than the persons above a median, but it is unknown whether they are in fact either high or low in self-esteem. All of the subjects might be rather high (or low). This method of assessing subjects is comparable to providing a measure of psychopathy to a sample of nuns to identify a group of psychopaths and nonpsychopaths, or a measure of altruism to convicts within a prison to identify a group of saints and sinners. Yet, many researchers will provide measures of self-esteem (self-monitoring, dependency, narcissism, or some other SRI measure) to a group of well-functioning college students to identify persons high and low in self-esteem. Baumeister et al. (1989) indeed found that "in all cases that we could determine, the sample midpoint was higher (in self-esteem) than the conceptual midpoint, and generally the discrepancy was substantial and significant" (p. 559).

3.07.2.4 Response Distortion

SRIs rely substantially on the ability of the respondent to provide a valid self-description. To the extent that a person does not understand the item, or is unwilling or impaired in his or her ability to provide an accurate response, the results will be inaccurate. "Detection of an attempt to provide misleading information is a vital and necessary component of the clinical interpretation of test results" (Ben-Porath & Waller, 1992, p. 24).

The presence of sufficiently accurate self-description is probably a reasonable assumption in most instances (Costa & McCrae, 1997). However, it may also be the case that no person will be entirely accurate in the description of this or her personality. Each person probably evidences some degree of distortion, either minimizing or exaggerating flaws or desirabilities. Such response distortion will be particularly evident in persons characterized by personality disorders (Westen, 1991). Antisocial persons will tend to be characteristically dishonest or deceptive in their self-descriptions, dependent persons may self-denigrate, paranoid persons will often be wary and suspicious, borderline persons will tend to idealize and devalue, narcissistic persons will often be arrogant or self-promotional, and histrionic persons will often be overemotional, exaggerated, or melodramatic in their self-descriptions (APA, 1994). Response distortion may also be common within some populations, such as forensic, disability, or psychiatric settings, due in part to the higher prevalence of personality disorder symptomatology within these populations but due as well to the pressures, rewards, and inducements within these settings to provide inaccurate self-descriptions (Berry, 1995).

A substantial amount of research has been conducted on the detection of response distortion (otherwise known as response sets or biases), particularly with the MMPI-2 (Butcher & Rouse, 1996). There are self-report scales to detect nonresponsiveness (e.g., random responding, yea-saying or nay-saying), overreporting of symptoms (e.g., malingering, faking bad, exaggeration, or self-denigration), and underreporting (e.g., faking good, denial, defensiveness, minimization, or self-aggrandizement). These scales often are referred to as validity scales, as their primary function has been to indicate the extent to which the scores on the personality (or clinical) scales are providing an accurate or valid self-description, and they do appear to be generally successful in identifying the respective response distortions (Berry, Wetter, & Baer, 1995).

However, it is not always clear whether the prevalence of a respective form of response distortion is frequent enough to warrant its detection within all settings (Costa & McCrae, 1997). Acquiescence, random responding, and nay-saying might be so infrequent within most settings that the costs of false positive identifications (i.e., identifying a personality description as invalid when it is in fact valid) will outweigh the costs of false negatives (identifying a description as valid when it was in fact invalid). In addition, much of the research on validity scales has been confined to analogue studies in which various response distortions are simulated by college students, psychiatric patients, or other persons. There is much less data to indicate that the inclusion of a validity scale as a moderator or suppressor variable actually improves the validity of the personality assessment. For example, it is unclear whether the correlation of a measure of the personality trait of neuroticism with another variable (e.g., drug usage) would increase when variance due to a response distortion (e.g., malingering or exaggeration) is partialled from the measure of neuroticism (Costa & McCrae, 1997).

In some contexts, such as a disability evaluation, response distortions are to be avoided, whereas in other contexts, such as the assessment of maladaptive personality traits, they may be what the clinician is seeking to identify (Ozer & Reise, 1994). Validity scales typically are interpreted as indicators of the presence of misleading or inaccurate information, but the response tendencies assessed by validity scales are central to some personality disorders. For example, an elevation on a malingering scale would indicate the presence of deception or dishonesty, suggesting perhaps that the information provided by the subject in response to the other SRI items was inaccurate or misleading. However, one might not want to partial the variance due to malingering from an SRI measure of antisocial or psychopathic personality. The validity of a measure of psychopathy would be reduced if variance due to deception or dishonesty was extracted, as dishonesty or deception is itself a facet of this personality syndrome (APA, 1994; Hare, 1991; Lilienfeld, 1994). It might be comparably misleading to extract variance due to symptom exaggeration from a measure of borderline personality traits, self-aggrandizement from a measure of narcissism, or self-denigration from a measure of dependency. Validity scales are not just providing a measure of response distortion that undermines the validity of personality description; they are also providing valid descriptions of highly relevant and fundamental personality traits.

For example, a response distortion that has been of considerable interest and concern is social desirability. Persons who are instructed to attribute falsely to themselves good, desirable qualities provide elevations on measures of social desirability, and many researchers have therefore extracted from a measure of personality the variance that is due to this apparent response bias. However, extracting this variance typically will reduce rather than increase the validity of personality measures because much of the socially desirable self-description does in fact constitute valid self-description (Borkenau & Ostendorf, 1992; McCrae & Costa, 1983). Persons who characteristically describe themselves in a socially desirable manner are not simply providing false and misleading information. Much of the variance within a measure of social desirability is due to persons either describing themselves accurately as having many desirable personality traits or, equally accurately, as having a personality disposition of self-aggrandizement, arrogance, or denial. This problem could be addressed by first extracting the variance due to valid individual differences from a measure of social desirability before it is used as a moderater variable, but then it might obviously fail to be useful as a moderater variable to the personality scales.

3.07.2.5 Automated Assessment and Base Rates

The structured nature of the responses to SRIs has also facilitated the development of automated (computerized) systems for scoring and interpretation. The researcher or clinician simply uses score sheets that can be submitted for computerized scanning, receiving in return a complete scoring and, in most cases, a narrative description of the subject's personality derived from the theoretical model of, and the data considered by, the author(s) of the computer system. Automated systems are available for most of the major personality SRIs, and their advantages are self-evident. "The computer can store and access a much larger fund of interpretive literature and base-rate data than any individual clinician can master, contributing to the accuracy, objectivity, reliability, and validity of computerized reports" (Keller, Butcher, & Slutske, 1990, p. 360).

Automated interpretive systems can also be seductive. They might provide the appearance of more objectivity and validity than is in fact the case (Butcher, 1995). Clinicians and researchers should always become closely familiar with the actual data and procedures used to develop an automated system, and the subsequent research assessing its validity, in order to evaluate objectively for themselves the nature and extent of the empirical support. For example,

> while any single clinician may do well to learn the norms and base rates of the client population he or she sees most often, a computer program can refer to a variety of population norms and, if programmed to do so, will always "remember" to tailor interpretive statements according to modifying demographic data such as education, marital status, and ethnicity. (Keller et al., 1990, p. 360)

This is an excellent sentiment, describing well the potential benefits of an automated report. However, simply providing a subject's education, marital status, and ethnicity to the automated computer system does not necessarily mean that this information will in fact be used. As noted above, very few of the SRIs consider ethnicity.

A purported advantage of the MCMI-III automated scoring system is that "actuarial base rate data, rather than normalized standard score transformations, were employed in calculating scale measures" (Millon et al., 1994, p. 4). The cutoff points used for the interpretation of the MCMI-III personality scales are based on the base rates of the personality syndromes within the population. "The BR [base rate] score was designed to anchor cut-off points to the prevalence of a particular attribute in the psychiatric population" (Millon et al., 1994, p. 26). This approach appears to be quite sophisticated, as it is seemingly responsive to the failure of clinicians and researchers to consider the effect of base rates on the validity of an SRI cutoff point (Finn & Kamphuis, 1995). "These data not only provide a basis for selecting optimal differential diagnostic cut-off scores but also ensure that the frequencies of MCMI-III diagnoses and profile patterns are comparable to representative clinical prevalence rates" (Millon et al., 1994 p. 4).

However, the MCMI-III automated scoring system does not in fact make adjustments to cutoff points depending upon the base rate of the syndrome within a local clinical setting. The MCMI-III uses the same cutoff point for all settings and, therefore, for all possible base rates. The advantage of setting a cutoff point according to the base rate of a syndrome is lost if the cutoff point remains fixed across different base rates (Finn & Kamphuis, 1995). "The use of the MCMI-III should be limited to populations that are not notably different in background from the sample employed to develop the instrument's base rate norms" (Millon et al., 1994, p. 35). It is for this reason that Millon et al. discourage the use of the MCMI-III within normal (community or college) populations (a limitation not shared by most other SRIs). In fact, the population sampled for the MCMI-III revision might have itself been notably different in background from the original sample used to develop the base rate scores. Retzlaff (1996) calculated the probability of having a personality disorder given the obtainment of a MCMI-III respective cutoff point, using the data provided in the MCMI-III test manual. Retzlaff concluded that "as determined by currently available research, the operating characteristics of the MCMI-III scales are poor" (p. 437). The probabilities varied from 0.08 to a high of only 0.32. For example, the probability of having an avoidant personality disorder if one surpassed the respective cutoff point was only 0.17, for the borderline scale it was only 0.18, and for the antisocial scale it was only 0.07. As Retzlaff indicated, "these hit rate statistics are well under one-half of the MCMI-II validities" (Retzlaff, 1996, p. 435).

Retzlaff (1996) suggested that there were two possible explanations for these results, either "the test is bad or that the validity study was bad" (p. 435) and he concluded that the fault lay with the MCMI-III cross-validation data. "At best, the test is probably valid, but there is no evidence and, as such, it cannot be trusted until better validity data are available" (Retzlaff, 1996, p. 435). However, it is unlikely that any new data will improve these statistics, unless the new study replicates more closely the population characteristics of the original derivation study. A third alternative is to have the cutoff points for the scales be adjusted for different base rates within local settings, but no automated scoring system currently provides this option.

3.07.2.6 Illustrative Instruments

There are many SRIs for the assessment of normal and maladaptive personality traits, including the SNAP (Clark, 1993), the DAPP-BQ (Livesley & Jackson, in press), the Personality Assessment Inventory (Morey, 1996), the MPQ (Tellegen & Waller, in press), the MCMI-III (Millon et al., 1994), the PDQ-4 (Hyler, 1994), the IAS (Wiggins & Trobst, 1997), the Wisconsin Personality Inventory (Klein et al., 1993), and the TCI (Cloninger & Svrakic, 1994). Space limitations prohibit a consideration of each of them. A brief discussion, however, will be provided for the two dominant SRIs within the field of clinical personality assessment, the MMPI-2 (Graham, 1993; Hathaway et al., 1989) and the NEO-PI-R (Costa & McCrae, 1992).

3.07.2.6.1 Minnesota Multiphasic Personality Inventory-2

The MMPI-2 is an SRI that consists of 566 true/false items (Graham, 1993; Hathaway et al., 1989). It is the most heavily researched and validated SRI, and the most commonly used in clinical practice (Butcher & Rouse, 1996). Its continued usage is due in part to familiarity and tradition, but its popularity also reflects the obtainment of a substantial amount of empirical support and normative data over the many years of its existence (Graham, 1993).

The MMPI-2 is described as "the primary self-report measure of abnormal personality" (Ben-Porath, 1994, p. 363) but its most common usage is for the assessment of anxiety, depressive, substance, psychotic, and other such (Axis I) mental disorders rather than for the assessment of personality traits (Ozer & Reise, 1994). "The MMPI-2 clinical scales are ... measures of various forms of psychopathology ... and not measures of general personality" (Greene, Gwin, & Staal, 1997, p. 21). This is somewhat ironic, given that it is titled as a personality inventory (Helmes & Reddon, 1993).

However, the MMPI-2 item pool is extensive and many additional scales have been developed beyond the basic 10 clinical and three validity scales (Graham, 1993). For example, some of the new MMPI-2 content scales (Ben-Porath, 1994; Butcher, 1995), modeled after the seminal research of Wiggins (1966), do assess personality traits (e.g., cynicism, social discomfort, Type A behavior, and low self-esteem). The Morey et al. (1985) personality disorder scales have also been updated and normed for the MMPI-2 (Colligan, Morey, & Offord, 1994) and an alternative set of MMPI-2, *DSM-IV* personality disorder scales are being developed by Somwaru and Ben-Porath (1995). Harkness and McNulty (1994) have developed scales (i.e., the PSY-5) to assess five broad domains of personality (i.e., neuroticism, extraversion, psychoticism, aggressiveness, and constraint) that are said to provide the MMPI-2 assessment of, or an alternative to, the five-factor model of personality (Ben-Porath, 1994; Butcher & Rouse, 1996). "Other measures of five-factor models of normal personality will need to demonstrate incremental validity in comparison to the full set of MMPI-2 scales (including the PSY-5) to justify their use in clinical practice" (Ben-Porath, 1994, p. 393). However, there are important distinctions between the PSY-5 and the five-factor model constructs, particularly for psychoticism and aggressiveness (Harkness & McNulty, 1994; Harkness, McNulty, & Ben-Porath, 1995; Widiger & Trull, 1997). In addition, the utility of the MMPI-2 for personality trait description and research may be limited by the predominance of items concerning clinical symptomatology and the inadequate representation of important domains of personality, such as conscientiousness (Costa, Zonderman, McCrae, & Williams, 1985) and constraint (DiLalla, Gottesman, Carey, & Vogler, 1993)

3.07.2.6.2 Neo Personality Inventory-Revised

The most comprehensive model of personality trait description is provided by the five-factor model (Saucier & Goldberg, 1996; Wiggins & Pincus, 1992). Even the most ardent critics of the five-factor model acknowledge its importance and impact (e.g., Block, 1995; Butcher & Rouse, 1996; Millon et al., 1996). And, the predominant measure of the five-factor model is the NEO-PI-R (Costa & McCrae, 1992, 1997; Ozer & Reise, 1994; Widiger & Trull, 1997).

The 240 item NEO-PI-R (Costa & McCrae, 1992) assesses five broad domains of personality: neuroticism, extraversion (vs. introversion), openness (vs. closedness), agreeableness (vs. antagonism), and conscientiousness. Each item is rated on a five-point scale, from strongly disagree to strongly agree. Each domain is differentiated into six underlying facets. For example, the six facets of agreeableness vs. antagonism are trust vs. mistrust, altruism vs. exploitiveness, compliance vs. oppositionalism or aggression, tender-mindedness vs. tough-mindedness (lack of empathy), modesty vs. arrogance, and straightforwardness vs. deception or manipulation. The domains and facets of the NEO-PI-R relate closely to other models of personality, such as the constructs of affiliation and power within the interpersonal circumplex model of personality (McCrae & Costa, 1989; Wiggins & Pincus, 1992). The NEO-PI-R assessment of the five-factor model also relates closely to the *DSM-IV* personality disorder nomenclature, despite its original development as a measure of normal personality functioning (Widiger & Costa, 1994).

The application of the NEO-PI-R within clinical settings, however, may be problematic, due to the absence of extensive validity scales to detect mood state and response-set distortion (Ben-Porath & Waller, 1992). A valid application of the NEO-PI-R requires that the respondent be capable of and motivated to provide a reasonably accurate self-description. This is perhaps a safe assumption for most cases (Costa & McCrae, 1997), but the NEO-PI-R might not be successful in identifying when this assumption is inappropriate. Potential validity scales for the NEO-PI-R, however, are being researched (Schinka, Kinder, & Kremer, 1997).

3.07.3 SEMISTRUCTURED INTERVIEWS

The single most popular method for clinical assessments of personality by psychologists working in either private practice, inpatient hospitals, or university psychology departments, is an unstructured interview (Watkins, Campbell, Nieberding, & Hallmark, 1995). Whereas most researchers of personality disorder rely upon semistructured interviews (SSI) (Rogers, 1995; Zimmerman, 1994), there are but a few SSIs for the assessment of normal personality functioning (e.g., Trull & Widiger, 1997) and none of the psychologists in a survey of practicing clinicians cited the use of a semistructured interview (Watkins et al., 1995).

Unstructured clinical interviews rely entirely upon the training, expertise, and conscientiousness of the interviewer to provide an accurate assessment of a person's personality. They are problematic for research as they are notoriously unreliable, idiosyncratic, and prone to false assumptions, attributional errors, and misleading expectations (Garb, 1997). For example, many clinical interviewers fail to provide a comprehensive assessment of a patient's maladaptive personality traits. Only one personality disorder diagnosis typically is provided to a patient, despite the fact that most patients will meet criteria for multiple diagnoses (Gunderson, 1992). Clinicians tend to diagnose personality traits and disorders hierarchically. Once a patient is identified as having a particular personality disorder (e.g., borderline), clinicians will fail to assess whether additional personality traits are present (Herkov & Blashfield, 1995). Alder, Drake, and Teague (1990) provided 46 clinicians with case histories of a patient that met the *DSM-III* criteria for four personality disorders (i.e., histrionic, narcissistic, borderline, and dependent). "Despite the directive to consider each category separately . . . most clinicians assigned just one [personality disorder] diagnosis" (Adler et al., 1990, p. 127). Sixty-five percent of the clinicians provided only one diagnosis, 28% provided two, and none provided all four.

Unstructured clinical assessments of personality also fail to be systematic. Morey and Ochua (1989) provided 291 clinicians with the 166 *DSM-III* personality disorder diagnostic criteria (presented in a randomized order) and asked them to indicate which personality disorder(s) were present in one of their patients and to indicate which of the 166 diagnostic criteria were present. Kappa for the agreement between their diagnoses and the diagnoses that would be given based upon the diagnostic criteria they indicated to be present, ranged from 0.11 (schizoid) to only 0.58 (borderline). In other words, their clinical diagnoses agreed poorly with their own assessments of the diagnostic criteria for each disorder. The results of this study were replicated by Blashfield and Herkov (1996). Agreement in this instance ranged from 0.28 (schizoid) to 0.63 (borderline). "It appears that the actual diagnoses of clinicians do not adhere closely to the diagnoses suggested by the [diagnostic] criteria" (Blashfield & Herkov, 1996, p. 226).

Clinicians often base their personality disorder assessments on the presence of just one or two features, failing to consider whether a sufficient number of the necessary features are present (Blashfield & Herkov, 1996). In addition, the one or two features that one clinician considers to be sufficient may not be consistent with the feature(s) emphasized by another clinician, contributing to poor interrater reliability (Widiger & Sanderson, 1995; Zimmerman, 1994) and to misleading expectations and false assumptions. For example, a number of studies have indicated that many clinicians tend to overdiagnose the histrionic personality disorder in females (Garb, 1997). Clinicians tend to perceive a female patient who has just one or two histrionic features as having a histrionic personality disorder, even when she may instead meet the diagnostic criteria for an alternative personality disorder (Blashfield & Herkov, 1996; Ford & Widiger, 1989; Morey & Ochoa, 1989). This overdiagnosis of histrionic personality disorder in females is diminished substantially when the clinician is compelled to assess systematically each one of the features. "Sex biases may best be diminished by an increased emphasis in training programs and clinical settings on the systematic use and adherence to the [diagnostic] criteria" (Ford & Widiger, 1989, p. 304).

The reluctance to use semistructured interviews within clinical practice, however, is understandable. Semistructured interviews that assess all of the *DSM-IV* personality disorder diagnostic criteria can require more than two hours for their complete administration (Widiger & Sanderson, 1995). This is unrealistic and impractical in routine clinical practice, particularly if the bulk of the time is spent in determining the absence of traits. However, the time can be diminished substantially by first administering an SRI to identify which domains of personality functioning should be emphasized and which could be safely ignored (Widiger & Sanderson, 1995).

Unstructured interviews are also preferred by clinicians because they find SSIs to be too constraining and superficial. Most clinicians prefer to follow leads that arise during an interview, adjusting the content and style to facilitate rapport and to respond to the particular needs of an individual patient. The questions provided by an SSI can appear, in comparison, to be inadequate and simplistic. However, SSIs are considered to be semistructured because they require (or allow) professional judgment and discretion in their administration and scoring. They are not simply mindless administrations of an SRI. The responsibility of an SSI interviewer is to assess for the presence of a respective trait, not to just record a subject's responses to a series of structured questions. Follow-up questions that must be sensitive and responsive to the mood state, defensiveness, and self-awareness of the person being interviewed are always required and are left to the expertise and discretion of the interviewer (Widiger, Frances, & Trull, 1989). There are only a few fully structured interviews for the assessment of personality traits and they may be inadequate precisely because of their excessive constraint and superficiality (Perry, 1992).

The questions provided by an SSI are useful in ensuring that each trait is assessed, and that a set of questions found to be useful in prior studies is being used in a consistent fashion. Systematic biases in clinical assessments are more easily identified, researched, and ultimately corrected with the explicit nature of SSIs and their replicated use across studies and research sites. A highly talented and skilled clinician can outperform an SSI, but it is risky to presume that one is indeed that talented clinician or that one is consistently skilled and insightful with every patient (Dawes, 1994). It would at least seem desirable for talented clinicians to be informed by a systematic and comprehensive assessment of a patient's personality traits.

3.07.3.1 Personality, Mood States, and Mental Disorders

Personality traits typically are understood to be stable behavior patterns present since young adulthood (Wiggins & Pincus, 1992). However, few SRIs emphasize this fundamental feature. For example, the instructions for the MMPI-2 make no reference to age of onset or duration (Hathaway et al., 1989). Responding true to the MMPI-2 borderline item, "I cry easily" (Hathaway et al., p. 6) could be for the purpose of describing the recent development of a depressive mood disorder rather than a characteristic manner of functioning. Most MMPI-2 items are in fact used to assess both recently developed mental disorders as well as long-term personality traits (Graham, 1993).

SRIs that required a duration since young adulthood for the item to be endorsed would be relatively insensitive to changes in personality during adulthood (Costa & McCrae, 1994), but SSIs are generally preferred over SRIs within clinical settings for the assessment of personality traits due to the susceptibility of SRIs to mood-state confusion and distortion (Widiger & Sanderson, 1995; Zimmerman, 1994). Persons who are depressed, anxious, angry, manic, hypomanic, or even just agitated are unlikely to provide accurate self-descriptions. Low self-esteem, hopelessness, and negativism are central features of depression and will naturally affect self-description. Persons who are depressed will describe themselves as being dependent, introverted self-conscious, vulnerable, and pessimistic (Widiger, 1993). Distortions will even continue after the remission of the more obvious, florid symptoms of depression (Hirschfeld et al., 1989).

Piersma (1989) reported significant decreases on the MCMI-II schizoid, avoidant, dependent, passive–aggressive, self-defeating, schizotypal, borderline, and paranoid personality scales across a brief inpatient treatment, even with the MCMI-II mood state correction scales. Significant increases were also obtained for the histrionic and narcissistic scales, which at first appeared nonsensical (suggesting that treatment had increased the presence of histrionic and narcissistic personality traits), until it was recognized that these scales include many items that involve self-confidence, assertion, and gregariousness. Piersma concluded that "the MCMI-II is not able to measure long-term personality characteristics ('trait' characteristics) independent of symptomatology ('state' characteristics)" (p. 91). Mood state distortion, however, might not be problematic within outpatient and normal community samples (Trull & Goodwin, 1993).

SSIs appear to be more successful than SRIs in distinguishing recently developed mental disorders from personality traits, particularly if the interviewers are instructed explicitly to make this distinction when they assess each item. Loranger et al. (1991) compared the assessments provided by the Personality Disorder Examination (PDE; Loranger, in press) at admission and one week to six months later. Reduction in scores on the PDE were not associated with depression or anxiety. Loranger et al. concluded that the "study provides generally encouraging results regarding the apparent ability of a particular semistructured interview, the PDE, to circumvent trait-state artifacts in diagnosing personality disorders in symptomatic patients" (p. 727).

However, it should not be presumed that SSIs are resilient to mood state distortions. O'Boyle and Self (1990) reported that "PDE dimensional scores were consistently higher (more symptomatic) when subjects were depressed" (p. 90) and Loranger et al. (1991) acknowledged as well that all but two of the PDE scales decreased significantly across the hospitalization. These changes are unlikely to reflect actual, fundamental changes in personality secondary to the brief psychiatric hospitalization.

The methods by which SRIs and SSIs address mood state and mental disorder confusion should be considered in future research (Zimmerman, 1994). For example, the *DSM-IV* requires that the personality disorder criteria be evident since late adolescence or young adulthood (APA, 1994). However, the PDE (Loranger, in press) requires only that one item be present since the age of 25, with the others present for only five years. A 45-year old adult with a mood disorder might then receive a dependent, borderline, or comparable personality disorder diagnosis by the PDE, if just one of the diagnostic criteria was evident since the age of 25.

3.07.3.2 Dissimulation and Distortion

Unstructured and semistructured interviewers base much of their assessments on the self-descriptions of the respondent. However, a substantial proportion of the assessment is also based on observations of a person's behavior and mannerisms (e.g., the schizotypal trait of odd or eccentric behavior; APA, 1994) the manner in which a person responds to questions (e.g., excessive suspiciousness in response to an innocuous question), and the consistency of the responses to questions across the interview. SSIs will also require that respondents provide examples of affirmative responses to ensure that the person understood the meaning or intention of a question. The provision of follow-up queries provides a significant advantage of SSIs relative to SRIs. For example, schizoid persons may respond affirmatively to an SRI question, "do you have any close friends," but further inquiry might indicate that they never invite these friends to their apartment, they rarely do anything with them socially, they are unaware of their friends' personal concerns, and they never confide in them. Widiger, Mangine, Corbitt, Ellis, and Thomas (1995) described a person who was very isolated and alone, yet indicated that she had seven very close friends with whom she confided all of her personal feelings and insecurities. When asked to describe one of these friends, it was revealed that she was referring to her seven cats.

In sum, none of the SSIs should or do accept a respondent's answers and self-descriptions simply at face value. Nevertheless, none of the personality disorder SSIs includes a formal method by which to assess defensiveness, dissimulation, exaggeration, or malingering. An assessment of exaggeration and defensiveness can be very difficult and complicated (Berry et al., 1995) yet it is left to the discretion and expertise of the interviewer in the assessment of each individual personality trait. Some interviewers may be very skilled at this assessment, whereas others may be inadequate in the effort or indifferent to its importance.

SSIs should perhaps include validity scales, comparable to those within self-report inventories. Alterman et al. (1996) demonstrated empirically that subjects exhibiting response sets of positive or negative impression management as assessed by the PAI (Morey, 1996) showed similar patterns of response distortion on two semistructured interviews, yet the interviewers appeared to be "essentially unaware of such behavior" (Alterman et al., 1996, p. 408). "The findings suggest that some individuals do exhibit response sets in the context of a structured interview and that this is not typically detected by the interviewer" (Alterman et al., 1996, p. 408). Much of the assessment of psychopathic personality traits by the revised Psychopathy Checklist (PCL-R; Hare, 1991) is based on a review of institutional file data rather than answers to interview questions, given the expectation that psychopathic persons will be characteristically deceptive and dishonest during an interview. It is unclear whether the PCL-R could provide a valid assessment of psychopathy in the absence of this additional, corrobatory information (Lilienfeld, 1994; Salekin, Rogers, & Sewell, 1996).

A notable exception to the absence of SSI validity scales is the Structured Interview of Reported Symptoms (SIRS; Rogers, Bagby, & Dickens, 1992) developed precisely for the assessment of subject distortion and dissimulation. The SIRS includes 172 items (sets of questions) organized into eight primary and five supplementary scales. Three of the primary scales assess for rare, improbable, or absurd symptoms, four assess for an unusual range and severity of symptoms, and the eighth assesses for inconsistencies in self-reported and observed symptoms. A substantial amount of supportive data has been obtained with the SIRS, particularly within forensic and neuropsychological settings (Rogers, 1995).

3.07.3.3 Intersite Reliability

The allowance for professional judgment in the selection of follow-up queries and in the interpretation of responses increases significantly the potential for inadequate interrater reliability. Good to excellent interrater reliability has been consistently obtained in the assessment of maladaptive personality traits with SSIs (Widiger & Sanderson, 1995; Zimmerman, 1994), but an SSI does not ensure the obtainment of adequate interrater reliability. An SSI only provides the means by which this reliability can be obtained. Most SSI studies report inadequate to poor interrater reliability for at least one of the domains of personality being assessed (see Widiger & Sanderson, 1995; Zimmerman, 1994). The obtainment of adequate interrater reliability should be assessed and documented in every study in which an SSI is being used, as it is quite possible that the personality disorder of particular interest is the one for which weak interrater reliability has been obtained.

The method by which interrater reliability has been assessed in SSI research is also potentially misleading. Interrater reliability has traditionally been assessed in SSI research with respect to the agreement between ratings provided by an interviewer and ratings provided by a person listening to an audiotaped (or videotaped) recording of this interview (Zimmerman, 1994). However, this methodology assesses only the agreement regarding the ratings of the respondents' statements. It is comparable to confining the assessment of the interrater reliability of practicing clinicians' personality assessments to the agreement in their ratings of a recording of an unstructured clinical interview. The poor interrater reliability that has been reported for practicing clinicians has perhaps been due largely to inconsistent, incomplete, and idiosyncratic interviewing (Widiger & Sanderson, 1995). It is unclear whether personality disorder SSIs have actually resolved this problem as few studies have in fact assessed interrater reliability using independent administrations of the same interview.

The misleading nature of currently reported SSI interrater reliability is most evident in studies that have used telephone interviews. Zimmerman and Coryell (1990) reported kappa agreement rates of 1.0 for the assessment of the schizotypal, histrionic, and dependent personality disorders using the Structured Interview for *DSM-III* Personality (SIDP; Pfohl, Blum, & Zimmerman, in press). However, 86% of the SIDP administrations were by telephone. Telephone administrations of an SSI will tend to be more structured than face-to-face interviews, and perhaps prone to brief and simplistic administrations. They may degenerate into a verbal administration of an SRI. Interrater agreement with respect to the ratings of subjects' affirmative or negative responses to MMPI-2 items (i.e., highly structured questions) is not particularly informative.

There is reason to believe that there might be poor agreement across research sites using the same SSI. For example, the prevalence rate of borderline personality disorder within psychiatric settings has been estimated at 15% (Pilkonis et al., 1995), 23% (Riso, Klein, Anderson, Ouimette, & Lizardi, 1994), 42% (Loranger et al., 1991), and 71% (Skodol, Oldham, Rosnick, Kellman, & Hyler, 1991), all using the same PDE (Loranger, in press). This substantial disagreement is due to many different variables (Gunderson, 1992; Pilkonis, 1997; Shea, 1995), but one distinct possibility is that there is an inconsistent administration and scoring of the PDE by Loranger et al. (1991), Pilkonis et al. (1995), Riso et al. (1994), and Skodol et al. (1991). Excellent interrater reliability of a generally unreliably administered SSI can be obtained within one particular research site through the development of local (idiosyncratic) rules and policies for the administration of follow-up questions and the scoring of respondents' answers that are inconsistent with the rules and policies developed for this same SSI at another research site.

3.07.3.4 Self and Informant Ratings

Most studies administer the SSI to the person being assessed. However, a method by which to address dissimulation and distortion is to administer the SSI to a spouse, relative, or friend who knows the person well. Many personality traits involve a person's manner of relating to others (McCrae & Costa, 1989; Wiggins & Trobst, 1997) and some theorists suggest that personality is essentially this manner of relating to others (Kiesler, 1996; Westen, 1991; Wiggins & Pincus, 1992).

A useful source for the description of these traits would then be persons with whom the subject has been interacting. These "informants" (as they are often identified) can be intimately familiar with the subject's characteristic manner of relating to them, and they would not (necessarily) share the subject's distortions in self-description. The use of peer, spousal, and other observer ratings of personality has a rich tradition in SRI research (Ozer & Reise, 1994).

An interview with a close friend, spouse, employer, or relative is rarely uninformative and typically results in the identification of additional maladaptive personality traits. However, it is unclear which source will provide the most valid information. Zimmerman, Pfohl, Coryell, Stangl, and Corenthal (1988) administered an SSI to both a patient and an informant, and obtained rather poor agreement, with correlations ranging from 0.17 (compulsive) to only 0.66 (antisocial). The informants identified significantly more dependent, avoidant, narcissistic, paranoid, and schizotypal traits, but Zimmerman et al. (1988) concluded that "patients were better able to distinguish between their normal personality and their illness" (p. 737). Zimmerman et al. felt that the informants were more likely to confuse patients' current depression with their longstanding and premorbid personality traits than the patients' themselves. Similar findings have been reported by Riso et al. (1994). Informants, like the patients themselves, are providing subjective opinions and impressions rather than objective descriptions of behavior patterns, and they may have their own axes to grind in their emotionally invested relationship with the identified patient. The fundamental attribution error is to overexplain behavior in terms of personality traits, and peers might be more susceptible to this error than the subjects themselves.

3.07.3.5 Convergent Validity Across Different Interviews

One of the most informative studies on the validity of personality disorder SSIs was provided by Skodol et al. (1991). They administered to 100 psychiatric inpatients two different SSIs on the same day (alternating in morning and afternoon administrations). Agreement was surprisingly poor, with kappa ranging from a low of 0.14 (schizoid) to a high of only 0.66 (dependent). Similar findings have since been reported by Pilkonis et al. (1995). If this is the best agreement one can obtain with the administration of different SSIs to the same persons by the same research team on the same day, imagine the disagreement that must be obtained by different research teams with different SSIs at different sites (however, both studies did note that significantly better agreement was obtained when they considered the dimensional rating of the extent to which each personality syndrome was present).

Skodol et al. (1991) concluded that the source of the disagreement they obtained between the Structured Clinical Interview for *DSM-III-R* Personality Disorders (SCID-II; First, Gibbon, Spitzer Williams, & Benjamin, in press) and the PDE (Loranger, in press) was the different questions (or items) used by each interview. "It is fair to say that, for a number of disorders (i.e., paranoid, schizoid, schizotypal, narcissistic, and passive–aggressive) the two [interviews] studied do not operationalize the diagnoses similarly and thus yield disparate results" (Skodol et al., p. 22).

There appear to be important differences among the SSIs available for the assessment of personality disorders (Clark,1992; Widiger & Sanderson, 1995; Zimmerman, 1994). Table 1 presents the number of structured questions (i.e., answerable by one word, such as "yes" or "frequently"), open-ended questions, and observational ratings provided in each of the five major personality disorder SSIs. It is evident from Table 1 that there is substantial variation across SSIs simply with respect to the number of questions provided, ranging from 193 to 373 with respect to structured questions and from 20 to 69 for open-ended questions. There is also variability in the reliance upon direct observations of the respondent. The PDE, Diagnostic Interview for *DSM-IV* Personality Disorders (DIPD-IV), and SIDP-IV might be more difficult to administer via telephone, given the number of observational ratings of behavior, appearance, and mannerisms that are required (particularly to assess the schizotypal and histrionic personality disorders).

There is also significant variability in the content of the questions used to assess the same personality trait (Clark, 1992; Widiger & Sanderson, 1995; Zimmerman, 1994). Table 2 presents the questions used by each of the five major SSIs to assess the borderline trait of identity disturbance, defined in *DSM-IV* as a markedly and persistently unstable sense of self-image or sense of self (APA, 1994). All five SSIs do ask about significant or dramatic changes in self-image across time. However, there are also notable differences. For example, the DIPD-IV and SIDP-IV refer specifically to feeling evil; the SIDP-IV highlights in particular a confusion regarding sexual orientation; the SCID-II appears to emphasize changes or fluctuations in self-image, whereas the DIPD-IV appears to emphasize an uncertainty or absence of self-image; and the Personality Disorder Interview-4 (PDI-IV) includes more open-ended self-descriptions.

It is possible that the variability in content of questions across different SSIs may not be as important as a comparable variability in questions across different SRIs, as the interviews may converge in their assessment through the unstructured follow-up questions, queries and clarifications. However, the findings of Pilkonis et al. (1995) and Skodol et al. (1991) suggest otherwise. In addition, as indicated in Table 1, most of the questions within the five SSIs are relatively structured, resulting perhaps in very little follow-up query.

3.07.3.6 Illustrative Instruments

The three most commonly used SSIs within clinical research for the assessment of the *DSM* personality disorders are the SIDP-IV (Pfohl et al., in press), the SCID-II (First et al., in press), and the PDE (Loranger, in press). The SIDP-IV has been used in the most number of studies. A distinctive feature of the PDE is the inclusion of the diagnostic criteria for the personality disorders of the World Health Organization's (WHO) *International Classification of Diseases* (*ICD-10*; 1992). However, using this international version of the PDE to compare the *DSM-IV* with the *ICD-10* is problematic, as the PDE does not in fact provide distinct questions for the *ICD-10* criteria. It simply indicates which of the existing PDE questions, developed for the assessment of the *DSM-IV* personality disorders, could be used to assess the *ICD-10* criteria. The *DSM-IV* and *ICD-10* assessments are not then independent. The DIPD (Zanarini, Frankenburg, Sickel, & Yong, 1996) is the youngest SSI, but it is currently being used in an extensive multi-site, longitudinal study of personality disorders.

3.07.3.6.1 SIDP-IV

The SIDP-IV (Pfohl et al., in press) is the oldest and most widely used SSI for the

Table 1 Amount of structure in personality disorder semistructured interviews.

Interview	*Number of questions*				*Observations*
	Structured	*Open-ended*	*Examples*	*Total*	
DIPD-IV	373	20	5	398	19
PDE	272	69	196	537	32
PDI-IV	290	35		325	3
SCID-II	193	35	75	303	7
SIDP-IV	244	58	35	337	16

Note. Examples = specified request for examples (PDI-IV instructs interviewers to always consider asking for examples, and therefore does not include a specified request for individual items); DIPD-IV = Diagnostic Interview for *DSM-IV* Personality Disorders (Zanarini et al., 1996); PDE = Personality Disorder Examination (Loranger, in press); PDI-IV = Personality Disorder Interview-4 (Widiger et al., 1995); SCID-II = Structured Clinical Interview for *DSM-IV* Axis II Personality Disorders (First, et al., in press); SIDP-IV = Structured Interview for *DSM-IV* Personality (Pfohl et al., in press).

assessment of the *DSM* personality disorders (Rogers, 1995; Widiger & Sanderson, 1995; Zimmerman, 1994). It includes 353 items (337 questions and 16 observational ratings) to assess the 94 diagnostic criteria for the 10 *DSM-IV* personality disorders. Additional items are provided to assess the proposed but not officially recognized negativistic (passive–aggressive), depressive, self-defeating, and sadistic personality disorders. It is available in two versions, one in which the items are organized with respect to the diagnostic criteria sets (thereby allowing the researcher to assess only a subset of the disorders) and the other in which the items are organized with respect to similar content (e.g., perceptions of others and social conformity) to reduce repetition and redundancy. Each diagnostic criterion is assessed on a four-point scale (0 = not present, 1 = subthreshold, 2 = present, 3 = strongly present). Administration time is about 90 minutes, depending in part on the experience of the interviewer and the verbosity of the subject. A computerized administration and scoring system is available. The accompanying instructions and manual are limited, but training videotapes and courses are available.

3.07.3.6.2 PDI-IV

The PDI-IV (Widiger et al., 1995) is the second oldest SSI for the assessment of the *DSM* personality disorders. It is comparable in content and style to the SIDP-IV, although it has fewer observational ratings and more open-ended inquiries. The PDI-IV has been used in substantially fewer studies than the SIDP-IV, PDE, or SCID-II, it lacks supportive training material, and only one of the published studies using the PDI-IV was conducted by independent investigators (Rogers, 1995). However, its accompanying manual is the most systematic and comprehensive, providing extensive information regarding the history, rationale, and common assessment issues for each of the *DSM-IV* personality disorder diagnostic criteria.

3.07.4 PROJECTIVE TECHNIQUES

Projective techniques are not used as often as SRIs in personality research, "and many academic psychologists have expressed the belief that knowledge of projective testing is not as important as it used to be and that use of projective tests will likely decline in the future" (Butcher & Rouse, 1996, p. 91). However, "of the top 10 assessment procedures [used by clinicians] ... 4 are projectives, and another (Bender-Gestalt) is sometimes used for projective purposes" (Watkins et al., 1995, p. 59). Butcher and Rouse (1996) document as well that the second most frequently researched clinical instrument continues to be the Rorschach. "Predictions about the technique's demise appear both unwarranted and unrealistic" (Butcher & Rouse, 1996, p. 91). "Whatever negative opinions some academics may hold about projectives, they clearly are here to stay, wishing will not make them go away ... and their place in clinical assessment practice now seems as strong as, if not stronger than, ever" (Watkins et al., 1995, p. 59).

The term "projective," however, may be somewhat misleading, as it suggests that these tests share an emphasis upon the interpretation of a projection of unconscious conflicts, impulses, needs, or wishes onto ambiguous stimuli. This is true for most projective tests but it is not in fact the case for the most commonly used scoring system (i.e., Exner, 1993) for the most commonly used projective test (i.e., the Rorschach). The Exner (1993) Comprehensive

Table 2 Semistructured interview questions for the assessment of identity disturbance.

DIPD-IV

1. During the past two years, have you often been unsure of who you are or what you're really like?
2. Have you frequently gone from feeling sort of OK about yourself to feeling that you're bad or even evil?
3. Have you often felt that you had no identity?
4. How about that you had no idea of who you are or what you believe in?
5. That you don't even exist?

PDE

1. Do you think one of your problems is that you're not sure what kind of person you are?
2. Do you behave as though you don't know what to expect of yourself?
3. Are you so different with different people or in different situations that you don't behave like the same person?
4. Have others told you that you're like that? Why do you think they've said that?
5. What would you like to accomplish during your life? Do your ideas about this change often?
6. Do you often wonder whether you've made the right choice of job or career? (If housewife, ask:) Do you often wonder whether you've made the right choice in becoming a housewife? (If student, ask:) Have you made up your mind about what kind of job or career you would like to have?
7. Do you have trouble deciding what's important in life?
8. Do you have trouble deciding what's morally right and wrong?
9. Do you have a lot of trouble deciding what type of friends you should have?
10. Does the kind of people you have as friends keep changing?
11. Have you ever been uncertain whether you prefer a sexual relationship with a man or a woman?

PDI-IV

1. How would you describe your personality?
2. What is distinct or unique about you?
3. Do you ever feel that you don't know who you are or what you believe in?
4. Has your sense of who you are, what you value, what you want from life, or what you want to be, been fairly consistent, or has this often changed significantly?

SCID-II

1. Have you all of a sudden changed your sense of who you are and where you are headed?
2. Does your sense of who you are often change dramatically?
3. Are you different with different people or in different situations so that you sometimes don't know who you really are?
4. Have there been lots of sudden changes in your goals, career plans, religious beliefs, and so on?

SIDP-IV

1. Does the way you think about yourself change so often that you don't know who you are anymore?
2. Do you ever feel like you're someone else, or that you're evil, or maybe that you don't even exist?
3. Some people think a lot about their sexual orientation, for instance, trying to decide whether or not they might be gay (or lesbian). Do you often worry about this?

Note. *DIPD-IV* = Diagnostic Interview for *DSM-IV* Personality Disorders (Zanarini et al., 1996, pp. 25–26); PDE = Personality Disorder Examination (Loranger, in press, pp. 58–60, 83, & 117); PDI-IV = Personality Disorder Interview-4 (Widiger et al., 1995, p. 92); SCID-II = Structured Clinical Interview for *DSM-IV* Axis II Personality Disorders (First et al., in press, p. 37); SIDP-IV = Structured Interview for *DSM-IV* Personality (Pfohl et al., in press, p. 19).

System does include a few scores that appear to concern a projection of personal needs, wishes, or preoccupations (e.g., morbid content) but much of the scoring concerns individual differences in the perceptual and cognitive processing of the form or structure of the shapes, textures, details, and colors of the ambiguous inkblots. Exner (1989) has himself stated that "unfortunately, the Rorschach has been erroneously mislabeled as a projective test for far too long" (p. 527).

The label "projective test" is also contrasted traditionally with the label "objective test" (e.g., Keller et al., 1990) but this is again misleading. The Exner (1993) Comprehensive System scoring for the Rorschach is as objective as the scoring of an MMPI-2 (although not as reliable). In addition, clinicians often can interpret MMPI-2 profiles in an equally subjective manner.

A more appropriate distinction might be a continuum of structure vs. ambiguity with respect to the stimuli provided to the subject and the range of responses that are allowed. Most of the techniques traditionally labeled as projective do provide relatively more ambiguous stimuli than either SRIs or SSIs (e.g., inkblots or drawings). However, many SRI items can be as ambiguous as an item from a projective test. Consider, for example, the MMPI-2 items "I like mechanics magazines," "I used to keep a diary," and "I would like to be a journalist" (Hathaway et al., 1989, pp. 5, 8, 9). These items are unambiguous in their content, but the trait or characteristic they assess is very ambiguous (Butcher, 1995). There is, perhaps, less ambiguity in the meaning of the stems provided in a sentence completion test, such as "My conscience bothered me most when," "I used to dream about" and "I felt inferior when" (Lah, 1989, p. 144) than in many of the MMPI-2 items.

SRIs, on the other hand, are much more structured (or constraining) in the responses that are allowed to these stimuli. The only responses can be "true" or "false" to an ambiguous MMPI-2 item, whereas anything can be said in response to a more obvious sentence completion stem. Projective tests are uniformly more open-ended than SRIs in the responses that are allowed, increasing substantially the potential for unreliability in scoring.

However, SSIs can be as open-ended as many projective tests in the responses that are allowed. For example, the PDI-IV SSI begins with the request of "having you tell me the major events, issues, or incidents that you have experienced since late childhood or adolescence" (Widiger et al., 1995, p. 245). This initial question is intentionally open-ended to ensure that the most important events or incidents are not neglected during the interview (Perry, 1992). However, such open-ended inquiries will contribute to problematic intersite reliability.

3.07.4.1 Rorschach

The Rorschach consists of 10 ambiguously shaped inkblots, some of which include various degrees of color and shading. The typical procedure is to ask a person what each inkblot might be, and to then follow at some point with inquiries that clarify the bases for the response (Aronow, Reznikoff, & Moreland, 1994; Exner, 1993). The Rorschach has been the most popular projective test in clinical practice since the Second World War, although the Thematic Apperception Test (TAT) and sentence completion tests are gaining in frequency of usage (Watkins et al., 1995).

There is empirical support for many Rorschach variables (Bornstein, 1996; Exner, 1993; Weiner, 1996), although the quality of some of this research has been questioned, including the support for a number of the fundamental Exner variables, such as the experience ratio (Kleiger, 1992; Wood, Nezworski, & Stejskal, 1996). The Rorschach can be administered and scored in a reliable manner, but the training that is necessary to learn how to score reliably the 168 variables of the Exner Comprehensive System is daunting, at best. SRIs and SSIs might provide a more cost-efficient method to obtain the same results (although profile interpretation of the MMPI-2 clinical scales can at times be equally complex; Helmes & Reddon, 1993). Exner (1996) has acknowledged, at least with respect to a depression index, that "there are other measures, such as the [MMPI-2], that might identify the presence of reported depression much more accurately than the Rorschach" (p. 12). The same point can perhaps be made for the assessment of personality traits, such as narcissism and dependency. Bornstein (1995), however, has argued that the Rorschach provides a less biased measure of sex differences in personality (dependency, in particular) because its scoring is less obvious to the subject. He suggested that the findings from SRIs and SSIs have provided inaccurate estimates of dependency in males because males are prone to deny the extent of their dependent personality traits in response to SRIs and SSIs.

An additional issue for the Rorschach is that its relevance to personality research and assessment is at times unclear. For example, the cognitive-perceptual mechanisms assessed by the Exner Comprehensive system do not appear to be of central importance to many theories of personality and personality disorder (Kleiger, 1992). "It is true that the Rorschach does not offer a precise measure for any single personality trait" (Exner, 1997, p. 41). How a person perceptually organizes an ambiguous inkblot may indeed relate to extratensive ideational activity, but constructs such as introversion, conscientiousness, need for affection, and empathy have a more direct, explicit relevance to current personality theory and research. More theoretically meaningful constructs are perhaps assessed by content (e.g., Aronow et al., 1994; Bornstein, 1996) or object-relational (e.g., Lerner, 1995) scoring systems. Content interpretations of the Rorschach are more consistent with the traditional understanding of the instrument as a projective stimulus, but this approach also lacks the empirical support of the cognitive-perceptual scoring systems and may only encourage a return to less reliable and subjective interpretations (Acklin, 1995).

3.07.4.2 Thematic Apperception Test

The TAT (Cramer, 1996) consists of 31 cards: one is blank, seven are for males, seven for females, one for boys or girls, one for men or women and one each for a boy, girl, man, and woman (the remaining 10 are for anyone). Thus, a complete set for any particular individual could consist of 20 stimulus drawings, although only 10 typically are used per person. Most of the drawings include person(s) in an ambiguous but emotionally provocative context. The instruction to the subject is to make up a dramatic story for each card, describing what is happening, what led up to it, what is the outcome, and what the persons are thinking and feeling. It is common to describe the task as a test of imaginative intelligence to encourage vivid, involved, and nondefensive stories.

The TAT is being used increasingly in personality research with an interpersonal or object-relational perspective (e.g., Westen, 1991). The TAT's provision of cues for a variety of interpersonal issues and relationships make it particularly well suited for such research, and the variables assessed are theoretically and clinically meaningful (e.g., malevolent vs. benevolent affect and the capacity for an emotional investment in relationships). The necessary training for reliable scoring is also less demanding than for the Rorschach, although a TAT administration remains time-consuming. There are many SRI measures of closely related interpersonal constructs that are less expensive and complex to administer and score (e.g., Kiesler, 1996; Wiggins & Trobst, 1997).

3.07.5 CONCLUSIONS

The assessment of personality is a vital component of clinical research and practice, particularly with the increasing recognition of the importance of personality traits to the development and treatment of psychopathology (Watson et al., 1994). The assessment of adaptive and maladaptive personality functioning is fundamental to virtually all fields of applied psychology.

It is then surprising and regrettable that clinical psychology training programs provide so little attention to the importance of and methods for obtaining comprehensive and systematic interviewing. The primary method for the assessment of personality in clinical practice is an unstructured interview that has been shown to be quite vulnerable to misleading expectations, inadequate coverage, and gender and ethnic biases. Training programs will devote a whole course, perhaps a whole year, to learning different projective techniques, but may never even inform students of the existence of any particular semistructured interview.

The preferred method of assessment in personality disorder research appears to be SSIs (Zimmerman, 1994), whereas the preferred method in normal personality research are SRIs (Butcher & Rouse, 1996). However, the optimal approach for both research and clinical practice would be a multimethod assessment, using methods whose errors of measurement are uncorrelated. No single approach will be without significant limitations. The convergence of findings across SRI, SSI, and projective methodologies would provide the most compelling results.

3.08.1 INTRODUCTION

The history of clinical psychology, similar to the history of medicine, has been characterized by the quest for knowledge of pathological processes. This knowledge enables practitioners in both fields to treat and prevent disorders that threaten the quality of life. Health practitioners must be able to identify and conceptualize the problem, communicate research and clinical findings to other members of their field, and ideally, to reach a scientific understanding of the disorder. Diagnostic taxonomies have evolved in part to achieve these goals (Millon, 1991). Classification systems have a long history, first in the basic sciences and medicine, and later in psychopathology. Modern psychopathology taxonomies owe much to the work of earlier medical diagnosticians, and their development has often paralleled that of medical systems (Clementz & Iacono, 1990). Both medical and psychopathological classification systems have served the purposes of improving diagnostic reliability, guiding clinical conceptualization and treatment, and facilitating research and scientific advancement (Blashfield, 1991; Clark, Watson, & Reynolds, 1995). Despite the usefulness of classification systems in psychopathology, no system is accepted universally. Furthermore, some have questioned the utility of classification systems as a whole, favoring behavioral descriptions of individual presentations instead (Kanfer & Saslow, 1965; Ullman & Krasner, 1975). The purpose of this chapter is to review the issues related to the assessment, diagnosis, and classification of psychopathology. The chapter will begin with a brief outline of the history of medical and psychopathological classification. Next, it will review the systems in use in the late 1990s, and evaluate these systems from the standpoint of clinical utility, research facilitation, and scientific understanding. It will then discuss the alternative approaches and future directions in the classification of psychopathology. Finally, the role of assessment strategies in informing this debate will be examined.

3.08.2 HISTORY OF CLASSIFICATION

3.08.2.1 Medical Classification

As Clementz and Iacono (1990) point out, medical classification systems have relied historically on careful observation of patients and their symptoms. The importance of observation as an adjunct to theorizing was recognized as long ago as the seventeenth century by thinkers such as Thomas Sydenham (1624–1689). Observations were used to make inferences about the causes of disease. The practice of medical observation and classification gained momentum with the advent of medical instruments. The most notable of these was the stethoscope, developed in 1819 by Rene Theophile Hyacinthe-Laennec (1787–1826). This advance in instrumentation led to the use of objective signifiers of pathology in diagnosing disease and a diminished interest in less technologically sophisticated observations or subjective reports of symptoms. The continuous development of new technologies increased the ability of physicians to determine the function of organs and their modes of operation when healthy. This novel conceptualization of dysfunction as related to the functioning of organs led the French physician Broussais (1772–1838) to propose the radical idea that specific symptom clusters could not define a disease adequately because of the high overlap between different disorders. He suggested that in order to identify a disease one needs to study the patient's physiological processes and constitution. Mid-nineteenth century advances in the various basic sciences (such as anatomy, histology, and biology) led to the further decline of the practice of observation in favor of the experimental study of physiological disease processes. Although this emphasis on understanding function was a great benefit to the various basic sciences, it culminated in the near abandonment of the practice of clinical observation (Clementz & Iacono, 1990). The increasing popularity of laboratory research also resulted in an emphasis on specific symptoms, rather than on the phenomenology of disease. This topographic or symptom-based approach to the study of pathology lent itself to a descriptive system of classification. However, this approach had its critics, as far back as the 1800s. Some investigators (e.g., Trousseau, 1801–1867) believed that a more comprehensive approach to diagnosis, incorporating both clinical observation and laboratory findings, would better allow the recognition of disorders and their treatment.

The field of genetics provided another major development in the science of classification. Mendel, working in an isolated monastery, pioneered the science of genetics. His efforts were continued by others (e.g., Garrod, 1902) who applied his work to humans. Watson and Crick's (1953a, 1953b) detailed description of the structure of human genetic material supplied yet another powerful tool for identifying the presence and etiology of certain disorders. A classification system based on genetic and biological etiology may seem promising. However, researchers soon realized that the specificity of genetics is less than perfect. This lack of specificity seemed particularly evident in the psychiatric disorders. We now know several psychiatric disorders are at least partly genetic. This is revealed by the finding that individuals with identical genetic make-up have higher concordance rates for developing the same disease than those who do not. However, because the concordance rate between identical twins is less than 100% (e.g., schizophrenia; Dworkin; Lenzenwenger, Moldin & Cornblatt, 1987), not all the variance in psychiatric disorders can be explained by genetic inheritance. These findings have led to the view that genetic make-up provides a diathesis for a particular disorder, which, when interacting with the environmental factors, may produce a disease.

3.08.2.2 Early Nosology of Psychopathology

Emil Kraepelin (1856–1926) was the first to adapt a medical classification framework for psychiatric illnesses (Blashfield, 1991; Kraepelin, 1971). He considered psychopathology to be the result of underlying disease states and advocated the scientific investigation of illnesses. He coined the term "dementia praecox" (later known as schizophrenia) to describe what had previously been considered distinct pathologies. Kraepelin's thinking regarding psychopathology and classification was shaped by the rapid advances in German medical science in the nineteenth century and by his training in behaviorism from Wilhelm Wundt (Berrios & Hauser, 1988). German medicine during Kraepelin's lifetime emphasized the interpretation of mental disorders as diseases of the brain (Menninger, 1963).

Kraepelin's training with Wundt contributed to his use of behavioral descriptions for clusters of symptoms he believed were linked by a common etiology. Kraepelin's psychopathology classification became influential through the publication of his textbooks on psychiatry. His categories later became the basis for the first official classification adopted by the American Psychiatric Association (APA) in 1917 (Menninger, 1963), and revised in 1932 (APA, 1933).

A contemporary of Kraepelin's, Sigmund Freud (1856–1939), was also influential in forming our understanding of psychopathology. In contrast to Kraepelin, Freud placed little emphasis on the phenomenology of disorders, stressing the importance of diagnoses based on the underlying cause of patients' manifest symptoms. Kraepelin, however, opposed Freudian theory and psychoanalytic practice because of its nonempirical orientation (Kahn, 1959). Freud's theories were well articulated, however, and by the 1950s had come to dominate American psychiatry (Blashfield, 1991). Psychoanalytic thought did not lose its foothold until the community-based mental health movement of the 1960s, which pointed out that psychoanalysis was only accessible to the wealthy. Other factors that contributed to the decline of psychoanalytic thought include the development of alternative interventions such as psychotropic medications and behavioral intervention, as well as a general shift toward empiricism. Around this time, there was a resurgence of Kraepelinian thought, mainly by a group of psychiatrists at Washington University in St. Louis (Robins & Guze, 1970). They believed that psychiatry had drifted too far from its roots in medicine, and that it was necessary to identify the biological bases of psychopathology. They advocated an emphasis on classification as a tool for helping psychopathology to evolve as a field (Blashfield, 1991; Klerman, 1978).

3.08.3 CLASSIFICATION OF MENTAL ILLNESS

3.08.3.1 History of Classification of Mental Illness

After World War II, the armed forces developed a more comprehensive nomenclature to facilitate the treatment of World War II servicemen. During this same period, the World Health Organization (WHO) published the first version of the *International classification of diseases* (*ICD-6*; WHO, 1992) that included psychiatric disorders. The authors of the *ICD-6* relied heavily on the work of various branches of the armed forces in the development of their taxonomy of psychopathology. The first version of the *Diagnostic and statistical manual of mental disorders* (*DSM*), a variant on the *ICD-6*, was published in 1952 by the APA's Committee on Nomenclature and Statistics. This nomenclature was designed for use in the civilian population, and focused on clinical utility (APA, 1994). The *DSM* (APA, 1994) was originally created as a means of standardizing the collection of statistics in psychiatric hospitals in the early 1900s. By the release of the second edition of the *DSM* (*DSM-II*) (1975), the authors had moved toward the elimination of exclusion rules and provision of more explicit and descriptive diagnostic criteria. The inclusion of explicit diagnostic criteria in the *DSM-II* was inspired by the 1972 work of a group of Neo-Kraeplinian theorists, Feighner, Baran, Furman, and Shipman at the Washington University School of Medicine in St. Louis (Feighner et al., 1972). This group had originally created a six-category system as a guideline for researchers in need of homogenous subject groups.

In 1978 and 1985, Spitzer and his colleagues modified and expanded the Washington University system and labeled it the Research Diagnostic Criteria (RDC). The RDC established criteria for 25 major categories, with an emphasis on the differential diagnosis between schizophrenia and the affective disorders. The authors of the *DSM-III* (1980) followed the example of the Washington University and RDC groups, including diagnostic criteria for each disorder and exclusion criteria for 60% of all *DSM-III* disorders. Most of these exclusion rules described hierarchical relationships between disorders, in which a diagnosis is not given if its symptoms are part of a more pervasive disorder.

As a result of these changes, the *DSM-III* and *DSM-III-R* are based almost exclusively on descriptive criteria. These criteria are grouped into distinct categories representing different disorders. The *DSM-IV* continues this tradition, using a categorical model in which patients are assigned to classes that denote the existence of a set of related signs and symptoms. The constituent signs and symptoms are thought to reflect an underlying disease construct. Researchers who advocate a categorical model of disease (e.g., Kraepelin) propose that disorders differ qualitatively from each other and from the nondisordered state. Although later editions of the *DSM* have relied progressively more on research findings in their formulation, the stated goal of *DSM-IV* remains the facilitation of clinical practice and communication (Frances et al., 1991). The *DSM* system has evolved as a widely used manual in both clinical and research settings. However, the structure and the stated goals of the *DSM* have been at the core of many controversies regarding the assessment, diagnosis, and classification of psychopathology.

3.08.3.2 Current Classification Systems

Two systems of classification are currently in common use: the *DSM-IV* (APA, 1994) and the ICD-10 (WHO, 1992). A detailed description of these systems is beyond the scope of this chapter and the interested reader should consult recent reviews of these systems (Frances, 1998; Regier, et al., 1998; Spitzer, 1998). A brief overview of each system is provided below.

The *DSM-IV* is a multiaxial classification system. The individual is rated on five separate axes. Axis I includes all diagnoses except personality disorders and mental retardation, the later being rated on Axis II. The rationale for the separation of these axes is to ensure that the presence of long-term disturbances is not overlooked in favor of current pathology. Together, these axes constitute the classification of abnormal behavior. The remaining three axes are not needed to make a diagnosis but contribute to the recognition of factors, other than the individuals' symptoms, that should be considered in determining the person's diagnosis. General medical conditions are rated on Axis III, psychosocial and environmental problems are coded on axis IV, and the individual's current level of functioning is rated on axis V.

The 10th Revision of the *ICD* (*ICD-10*) is a multiaxial system. Axis I includes clinical diagnoses for both mental and physical disorders, Axis II outlines disabilities due to impairments produced by the disorder, and Axis III lists the environmental, circumstantial, and personal lifestyle factors that influence the presentation, course, or outcome disorders. *ICD-10* differs from other multiaxial classifications in that it: (i) records all medical conditions on the same axis (Axis I), (ii) assesses comorbid disorders (Axis II) in specific areas of functioning without ascribing a specific portion to each disorder, and (iii) allows expression of environmental (Axis III) factors determined by clinical practice and epidemiological evidence (Janca, Kastrup, Katschnig, Lopez-Ibor, 1996).

One purpose for the collaboration between *DSM-IV* and *ICD-10* authors was to foster the goal of the transcultural applicability of *ICD-10* (Uestuen, Bertelsen, Dilling, & van Drimmelen, 1996). A multiaxial coding format in both *DSM-IV* and *ICD-10* was adopted in order to provide unambiguous information with maximum clinical usefulness in the greatest number of cases (WHO, 1996). Although not explicitly stated by the authors of either manual, both the *DSM-IV* and *ICD-10* are examples of the "neo-Kraepelinian revolution" in psychiatric diagnostic classification (Compton & Guze, 1995).

The progress toward the shared goals of the two systems include two areas: general clinical use of the systems; and fostering international communication and cultural sensitivity. Regarding general clinical use, a multicenter field trial evaluating aspects of the *ICD-10* and *DSM-IV* involving 45 psychiatrists and psychologists in seven centers was conducted in Germany (Michels et al., 1996). Results revealed moderate inter-rater reliability for the *ICD-10* Axis I and Axis II. However, the number of relevant psychosocial circumstances coded on Axis III by the different raters varied greatly. The authors concluded that the multiaxial system was generally well accepted by participating clinicians, and that it is worth studying empirically and revising accordingly.

Clinicians specializing in several specific areas have not been as positive in their comments about the *ICD-10*. For instance, Jacoby (1996) has argued that neither the *DSM-IV* nor the *ICD-10* is adequate in its categorization of certain disorders associated with the elderly, such as certain dementias and psychotic disorders. Others have argued that specific *ICD-10* diagnoses show poor levels of stability of diagnosis across time. Specifically, a 1997 study found that neurotic, stress-related, adjustment, generalized anxiety, and panic disorders as well as some psychoses and personality disorders showed low rates of reliability across interviews at different time points (Daradkeh, El-Rufaie, Younis, & Ghubash, 1997).

Issues regarding the fostering of international communication and cultural sensitivity were addressed by a Swiss study published in 1995 that assessed the inter-rater reliability and confidence with which diagnoses could be made using the *ICD Diagnostic Criteria for Research* (*ICD-10 DCR*), as well as examining the concordance between *ICD-10 DCR*, *ICD-10 Clinical Descriptions and Diagnostic Guidelines*, and other classification systems including the *DSM-IV*. Field trials were carried out at 151 clinical centers in 32 countries by 942 clinician/researchers who conducted 11 491 individual patient assessments. The authors report that most of the clinician/researchers found the criteria to be explicit and easy to apply and the inter-rater agreement was high for the majority of diagnostic categories. In addition, their results suggested that the use of operational criteria across different systems increases levels of inter-rater agreement.

Regier, Kaelber, Roper, Rae, and Sartorius (1994) cited findings suggesting that while overall inter-rater reliability across 472 clinicians in the US and Canada was good, the clinician tended to make more use of multiple coding for certain disorders than clinicians from other countries. This suggests that certain aspects of the *DSM* system (e.g., its encouragement of multiple diagnoses) may make the transition and agreement between the two systems somewhat more difficult.

The *ICD's* efforts to place psychiatric disorders in the context of the world community's different religions, nationalities, and cultures has received praise in the literature (Haghighat, 1994), while the *DSM-IV* may be seen as somewhat less successful in achieving this goal. The *ICD's* increased cultural sensitivity was at the expense of increased length, but efforts to omit cultural-biased criteria were largely successful. However, other authors have argued that the attempts to improve cultural sensitivity to the degree of a "universal" understanding of mental illness may be misguided (Patel & Winston, 1994). Specifically, while mental illness as a phenomenon may be universal, specific categories of mental illness as outlined by the *DSM* and *ICD* may require identification and validation of particular diagnoses within specific cultures (Patel & Winston, 1994).

3.08.3.3 Tools for Clinical Assessment

A comprehensive review of assessment measures for psychopathology is beyond the scope of this chapter. The interested reader should consult comprehensive reviews of this topic (e.g., Baumann, 1995; Bellack & Hersen, 1998; Sartorius & Janca, 1996). One useful method of classifying assessment techniques is to consider two classes of measures: those that aim to aid in diagnosis and those that aim to assess the severity of symptoms relatively independent of diagnosis. Examples of the first category include The Structured Clinical Interview for *DSM-IV* Diagnoses (SCID; First, Spitzer, Gibbon, & Williams, 1995) and the Composite International Diagnostic Interview (CIDI; Robins et al., 1988). These measures are mapped closely on the diagnostic systems on which they are based (*DSM-IV* and *ICD-10*, respectively). The second class of assessment instruments use a dimensional approach and aim to assess severity of symptoms relatively independently of diagnosis. Examples of such instruments include the Hamilton Depression Inventory (HAM-D; Riskind, Beck, Brown, & Steer, 1987) and the Yale-Brown Obsessive-Compulsive Scale (Y-BOCS; Goodman, Price, Rasmussen, & Mazure, 1989a). The advantages and disadvantages of these assessment techniques are tied closely to advantages and disadvantages of the categorical and dimensional approaches to classification and will be discussed in Section 3.08.5.2.3.

An important aspect of developing new knowledge in psychopathology is the improvement and standardized use of assessment tools across studies of psychopathology. The vast majority of studies of *DSM* disorders have used self-report or interview-based measures of symptoms. In some cases, behavioral checklists (either self- or other-reports) or psychological tests have been employed. In this section, issues such as the accuracy, reliability, and discriminate validity of such assessment tools and how they may influence findings in psychopathology studies will be examined.

Self-report measures may be the most time- and labor-efficient means of gathering data about psychological symptoms and behaviors. However, individuals often are inconsistent in their observations of their own behaviors, and the usefulness of these reports depends heavily on often limited powers of self-observation. Psychometric methods for enhancing the usefulness of self-report data generally focus on increasing the consistency (i.e., reliability and accuracy or validity) of the measures. A number of psychometrically sophisticated scales are available for several different types of disorders (e.g., anxiety; BAI; Beck, Epstein, Brown, & Steer, 1988; PSS; Foa, Riggs, Dancu, & Rothbaum, 1993; Y-BOCS; Goodman et al., 1989a, 1989b). Many of the traditional psychometric approaches classify disorders into state (transitory feelings) and trait (stable personality) attributes (e.g., state anxiety vs. trait anxiety, STAI; Spielberger, Gorsuch, & Lushene, 1970). The accuracy of these scales is most often evaluated by comparing results on the measure to results on other measures of the same emotion or disorder (e.g., interviews, physiological assessments, observations of behavior). By assessing various aspects of an emotion or disorder, the investigator tries to create a composite gauge of an emotion for which no single indicator offers a perfect yardstick.

One impediment to discovering which symptoms may be shared across disorders has been the structure of many clinical measures. Examples of widely-used measures of psychological states are the Beck Depression Inventory (BDI; Beck & Steer, 1987), the Beck Anxiety Inventory (BAI; Beck et al., 1988), the Minnesota Multiphasic Personality Inventory (MMPI-2; Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989), and structured interview scales such as the Diagnostic Inventory Scale (DIS; Helzer & Robins, 1988) and the Structured Clinical Interview for *DSM-IV* Diagnoses (SCID; First et al., 1995).

These self-report and clinician-rated scales usually assess "modal" symptoms, as they focus on core aspects of each syndrome rather than on all possible variants. Structured interviews, such as the SCID-IV or the DIS, often allow "skip outs" in which the interviewer need not necessarily assess all of the symptoms of all disorders. Many studies have examined the convergent and divergent validity patterns of self-report (e.g., modal) measures of various disorders (e.g., Foa et al., 1993). These measures tend to yield strongly convergent assessments of their respective syndromes, but there is little specificity in their measurement, especially in nonpatient samples. The data often suggest the presence of a large nonspecific component shared between syndromes such as anxiety and depression (Clark & Watson, 1991). Some scales appear to be more highly loaded with the nonspecific distress factor than others. Therefore, in order to efficiently discriminate between disorders, future research should emphasize identification of symptoms which optimally discriminate between diagnoses. Watson and Clark (1992) found that even when factor analytically derived mood measures such as the Profile of Moods (POMS; McNair, Lorr, & Droppleman, 1981) and the Positive and Negative Affectivity Scale (PANAS; Watson, Clark, & Tellegen, 1988) are used, certain basic affects (i.e., anxiety and depression) are only partially differentiable. Their data suggest that the overlap between basic affects represents a shared component inherent in each mood state, which must be measured in order to understand the overlap between different mood states and disorders.

3.08.4 CURRENT ISSUES IN THE CLASSIFICATION OF PSYCHOPATHOLOGY

As noted earlier, the classification of psychopathology has been a controversial topic since inception. Currently, the discussions revolve primarily around the *DSM* system, although many of the debates predate the *DSM*. The most common topics of controversy in the classification of psychopathology are: (i) the definition of psychopathology; (ii) the artificially high rates of comorbidity found between disorders when using the *DSM* system (Frances, Widiger, & Fyer, 1990; Robins, 1994; (iii) the balance between a focus on clinical utility and the facilitation of research and scientific progress (Follette, 1996); and (iv) organizational problems, both within and across disorders in the *DSM* (Brown & Barlow, 1992; Quay, Routh, & Shapiro, 1987).

3.08.4.1 Definition of Psychopathology

There is a lack of agreement about the definition of psychopathology. Early versions of both the *ICD* and the *DSM* attempted to guide the categorization of mental disorders without addressing the definition of psychopathology (Spitzer, Endicott, & Robins, 1978). Some contend that this lack of agreement about the definition of psychopathology remains the current state of affairs (e.g., Bergner, 1997). Others (e.g., Kendell, 1975, 1982) have noted that physicians frequently diagnose and treat disorders for which there is no specific definition, and which, in many cases, are not technically considered disorders (e.g., pregnancy). The controversy over the definition of mental disorder may be fueled by the fact that such illnesses are signified commonly by behaviors, and distinguishing between "normal" and "deviant" or "disordered" behaviors is viewed by some as having serious cultural and sociological implications (Mowrer, 1960; Szasz, 1960). According to Gorenstein (1992), attempts at defining mental illness have fallen historically into several categories. Some have relied on statistical definitions based on the relative frequency of certain characteristics in the general population. Others have employed a social definition in which behaviors which conflict with the current values of society are considered deviant. Still other approaches have focused on the subjective discomfort caused by the problem, as reported by the individual. Finally, some definitions of psychopathology have been based on psychological theories regarding states or behaviors thought to signify problems within the individual. The *DSM-IV* (APA, 1994) defines a mental disorder as a "clinically significant behavioral or psychological syndrome or pattern that occurs in an individual and ... is associated with present distress ... or disability ... or with a significant increased risk of suffering death, pain, disability or an important loss of freedom." The disorder should not be an "expectable and culturally sanctioned response to an event," and must be considered a manifestation of dysfunction in the individual. Wakefield has expanded and refined this idea in his concept of "harmful dysfunction" (Wakefield, 1992, 1997c). This concept is a carefully elaborated idea considered by some to be a workable solution to the problem of defining abnormality (e.g., Spitzer, 1997). In essence, the harmful dysfunction concept means that behaviors are abnormal to the extent that they imply something is not working properly as would be expected based on its evolutionary function. Specifically, Wakefield (1992) states that a mental disorder is present

> if and only if, a) the condition causes some harm or deprivation of benefit to the person as judged by the standards of the person's culture (the value criteria), and b) the condition results from the inability of some mental mechanism to perform its natural function, wherein a natural function is an effect that is part of the evolutionary explanation of the existence and structure of the mental mechanism (the explanatory criterion). (p. 385)

Critics of Wakefield's concept argue that it represents a misapplication of evolutionary theory (Follette & Houts, 1996). They contend that evolutionary selection was not meant to apply on the level of behavioral processes, that is, it is not possible to know the function of a part or process of the individual by examining evolutionary history because random variation precludes a straightforward interpretation of the "design" of various parts of organisms (Mayr, 1981; Tattersall, 1995). Proponents of the "harmful dysfunction" definition suggest that it may provide a useful starting point for research in psychopathology, although further research needs to identify the specific mechanisms that are not functioning properly (Bergner, 1997).

3.08.4.2 Comorbidity

The term comorbidity was first used in the medical epidemiology literature and has been defined as "the co-occurrence of different diseases in the same individual" (Blashfield, 1990; Lilienfeld, Waldman, & Israel, 1994). Many factors potentially may contribute to the comorbidity rates of psychiatric disorders. Reported comorbidity rates are influenced by the actual co-occurrence of disorders, the populations considered, the range, severity, and base rates of the disorders considered, the method of assessment, and the structure of the classification system used.

3.08.4.2.1 Actual co-occurrence of disorders

In the medical literature, comorbidity often refers to diagnoses which occur together in an individual, either over one's lifetime or simultaneously. This concept emphasizes the recognition that different diagnoses potentially are related in several ways. One disease can signal the presence of another, predispose the patient to the development of another, or be etiologically related to another disorder (Lilienfeld et al., 1994). Lilienfeld et al. suggest that the increased attention to comorbidity in psychopathology is due to acknowledgment of the extensive co-occurrence and covariation that exists between diagnostic categories (Lilienfeld et al. ; Widiger & Frances, 1985). For example, Kessler et al. (1994) reported the results of a study on the lifetime and 12-month prevalence of *DSM-III-R* disorders in the US, in a random sample of 8098 adults. Forty-eight percent of the subjects reported at least one lifetime disorder, with the vast majority of these individuals, 79%, reporting comorbid disorders. Other studies using large community samples report that more than 50% of the participants diagnosed with one *DSM* disorder also meet criteria for a second disorder (Brown & Barlow, 1992). It has been argued that the common etiological factors across different diagnoses are of greater importance than the etiological factors specific to one disorder (Andrews, 1991; Andrews, Stewart, Morris-Yates, Holt, & Henderson, 1990).

3.08.4.2.2 Populations considered

One factor that affects comorbidity rates is the population under study. Kessler et al. (1994) found that people with comorbid disorders were likely to report higher utilization of services than those without a comorbid disorder. Similarly, higher rates of comorbidity were found among urban populations than rural populations, despite the higher rates of single psychiatric disorders and financial problems among rural participants. The race of the population studied also seems to influence comorbidity rates. African-American participants in the Kessler et al. study reported lower comorbidity rates than Caucasian participants, after controlling for the effects of income and education. However, Caucasian participants reported lower rates of current comorbid disorders than Hispanics. Disparities in prevalence of reported comorbidity were also found between respondents of different age groups, with people aged between 25 and 34 years reporting the highest rates. The income and education of the participants were also associated with reported comorbidity in the Kessler et al. study.

3.08.4.2.3 Range, severity, and base rates of disorders considered

The rates of comorbidity are also influenced by the disorders studied. Specifically, the range, severity, and base rates of certain disorders increase the likelihood that these disorders will be comorbid with another disorder. Certain diagnostic categories, including childhood disorders (Abikoff & Klein, 1992; Biederman, Newcorn, & Sprich, 1991), anxiety disorders (Brown & Barlow, 1992; Goldenberg et al., 1996), and personality disorders (Oldham et al., 1992; Widiger & Rogers, 1989), appear to be comorbid with other disorders. For example, 50% of patients with a principal anxiety disorder reported at least one additional clinically significant anxiety or depressive disorder in a large-scale study by Moras, DiNardo, Brown, and Barlow (1991). Similarly, anxiety disorders are not only highly likely to be comorbid with each other but also with mood, substance use, and personality disorders (Brown & Barlow, 1992). These high rates of comorbidity may in part be due to the degree to which the different anxiety disorders include overlapping features (Brown & Barlow, 1992). Finally the degree of comorbidity is influenced directly by thresholds set to determine the presence or absence of various disorders. The choice of threshold appears to affect comorbidity rates differentially, depending on the disorder. For instance, certain disorders (e.g., social phobia) appear to be more likely to accompany other anxiety disorders when considered at subclinical levels (Rapee, Sanderson, & Barlow, 1988). Conversely, Frances et al. (1990) have suggested that the severity of mental health problems in a sample will influence comorbidity rates, in that a patient with a severe presentation of one disorder is more likely to report other comorbid disorders.

In addition to the range and severity thresholds of disorders, the base rates of a particular disorder have a strong influence on the apparent comorbidity rates. Conditions that are frequently present in a given sample will tend to be diagnosed together more often than those that are infrequent. This may help explain the comorbidity rates of certain highly prevalent disorders such as anxiety, depression, and substance abuse.

3.08.4.2.4 Assessment methods

The choice of assessment methods may influence comorbidity rates in much the same way as aspects of the disorders. Disagreement regarding comorbidity rates may be partly due to differences in the definition of comorbidity. For example, comorbidity has been defined as within-episode co-occurrence (or dual diagnosis) among disorders by some (August & Garfinkel, 1990; Fulop, Strain, Vita, Lyons, & Hammer, 1987), lifetime co-occurrence by others (Feinstein, 1970; Shea, Widiger, & Klein, 1992, p. 859), and covariation among diagnoses (i.e., across individuals) by still other researchers (Cole & Carpentieri, 1990; Lewinsohn, Rohde, Seeley, & Hops, 1991). Even when researchers agree on a definition, their estimates of comorbidity may differ based on the type of assessment tool they use. As Lilienfeld et al. (1994) point out, assessment techniques have error variance that by definition is not related to the construct(s) of interest or may artificially inflate the actual comorbidity rate.

Furthermore, individual raters may hold biases or differing endorsement thresholds for behaviors which are common to a variety of disorders. Likewise, raters may have specific beliefs about which disorders tend to covary. These types of biases may affect both self-report and interviewer-based data. Similarly, studies utilizing structured interviews may differ from studies in which severity thresholds are not described as concretely. Therefore, differing rates of comorbidity across studies may be an artifact of the types of measurement used, or the biases of raters involved (Zimmerman, Pfohl, Coryell, Corenthal, & Stangl, 1991).

3.08.4.2.5 Structure of the classification system

Frances et al. (1990) argue that the classification system used in the various versions of the *DSM* increases the chance of comorbidity in comparison to other, equally plausible systems. The early systems (e.g., *DSM-III*) attempted to address the comorbidity issue by proposing elaborate hierarchical exclusionary rules specifying that if a disorder was present in the course of another disorder that took precedence, the second disorder was not diagnosed (Boyd et al., 1984). Thus, disorders which may have been truly comorbid were overlooked. Examination of these issues resulted in the elimination of this exclusionary criterion in *DSM-III-R*. This new method of diagnosis, however, has been criticized for artificially inflating comorbidity between various disorders.

Frances et al. (1990) point out that new editions of the *DSM* expanded coverage by adding new diagnoses. This was done by "splitting" similar disorders into subtypes. They argue that the tendency to split diagnoses creates much more comorbidity than would "lumping" systems of classification. This is because disorders that share basic underlying features are viewed as separate.

Much of the "splitting" in the *DSM* has resulted from the increasing reliance on prototypical models of disorders (Blashfield, 1991). The creators of the *DSM* increasingly have relied on prototypes, defining a diagnostic category by its most essential features, regardless of whether these features are also present in other diagnoses. McReynolds (1989) argued that categories with a representative prototype and indistinct or "fuzzy" boundaries are the basis of the most utilitarian classification systems because they are representative of categories in nature. The use of this type of prototype-based classification has improved the sensitivity and clinical utility of the *DSM* system. However, these gains are achieved at the expense of increased comorbidity and decreased specificity of differential diagnosis due to definitional overlap. Thus, this system of diagnostic classification makes it unclear whether there is any true underlying affinity between disorders currently considered to have high rates of comorbidity.

The stated approach of the *DSM-IV* is a descriptive method relying on observable signs and symptoms rather than underlying mechanisms. The sets of signs and symptoms that constitute the different diagnoses are, by definition, categorical, that is, the presence of the required number and combination of symptoms indicates a diagnosis and the absence of the required number of symptoms precludes a diagnosis. The symptoms are not weighted, implying that they are of equal importance in defining the disorder. For many diagnoses, the structure of this system makes it possible for two individuals to meet the same diagnostic criteria without sharing many symptoms. Conversely, it is possible for one person to meet the criteria while another person who shares all but one feature does not meet the criteria. As a result, patients who actually form a fairly heterogeneous group may be "lumped" into one homogeneous diagnostic category.

Combined with unweighted symptoms and a lack of attention to severity of symptoms, this "lumping" can lead to what Wakefield (1997a) refers to as "overinclusiveness" of diagnostic criteria. Specifically, people who do not truly suffer from a mental disorder may nonetheless receive the diagnosis, thus lowering the conceptual validity of *DSM* diagnostic categories. Conversely, minute differences in reported symptoms may result in dichotomizing between disordered and nondisordered individuals, or between individuals with one disorder as opposed to another (e.g., avoidant personality disorder vs. generalized social phobia), creating heterogeneity where there may actually be none.

This point is further elaborated by Clark et al. (1995), who point out that within-category heterogeneity constitutes a serious challenge to the validity of the *DSM*. These authors view comorbidity and heterogeneity as related problems, that is, within-group heterogeneity of symptoms found across diagnostic categories leads to increased rates of comorbidity among the disorders. Homogenous categories, on the other hand, lead to patient groups that share defining symptoms and produce lower rates of both comorbidity and heterogeneity. This is in part because of polythetic systems that require some features of a disorder for diagnosis. In contrast, a monothetical system would require all features of a disorder for diagnosis. Because the monothetic approach to diagnosis produces very low base rates for any diagnosis (Morey, 1988), researchers generally have used the polythetic approach. However, this approach promotes within-category heterogeneity because individuals who do not share the same symptom profiles can receive the same diagnosis. This poses a problem for any categorical system, including the *DSM*. Because of the inherent heterogeneity in patient profiles, a categorical system must address this issue by either proposing artificial methods of limiting heterogeneity (e.g., *DSM-III*), using unrealistic homogeneous categories, or acknowledging the heterogeneity (e.g., *DSM-IV*; Clark et al., 1995). Schizophrenia is an example of a diagnosis that has proved to have within-group heterogeneity. For example, current nosology (e.g., *DSM-IV*) assumes that schizophrenia and affective illness are distinct disorders. However, shared genetic vulnerability has been proposed for schizophrenia and some affective disorders (Crow, 1994). Taylor (1992) reviewed the evidence for this continuum and suggested that the discrimination of these disorders by their signs and symptoms is inadequate (Taylor & Amir, 1994). The need to know whether psychoses vary along a continuum is obviously critical to our understanding of their pathogenesis and etiology.

To address within-group heterogeneity of disorders, researchers have attempted to create subtypes (e.g., positive vs. negative symptoms of schizophrenia; Andreasen, Flaum, Swayze, Tyrell, & Arndt, 1990). Consistent with this conceptualization, researchers have correlated negative symptoms of schizophrenia with cognitive deficits (Johnstone et al., 1978), poor premorbid adjustment (Pogue-Geile & Harrow, 1984), neuropathologic and neurologic abnormalities (Stevens, 1982), poor response to neuroleptics (Angrist, Rotrosen, & Gershon, 1980), and genetic factors (Dworkin & Lenzenweger, 1984). On the other hand, positive symptoms have been correlated with attention (Cornblatt, Lenzenweger, Dworkin, Erlenmeyer-Kimling, 1992) and a positive response to neuroleptics (Angrist et al., 1980). Despite these differences, some investigators have questioned the reliability of these findings (Carpenter, Heinrichs, & Alphs, 1985; Kay, 1990) and the clinical clarity of the subtypes (Andreasen et al., 1990). The majority of these studies included patients with schizophrenia but not affective disorders, and some assessed only limited symptoms (e.g., only negative symptoms; Buchanan & Carpenter, 1994; Kay, 1990). These approaches are potentially problematic because they assume implicitly that the psychoses are distinct, and that the specific types of psychopathology are easily discriminated.

In summary, the issue of comorbidity poses what is potentially the greatest challenge to diagnosis. Factors including the populations considered, the range, severity, and base rates of the disorders considered, the method of assessment, and the structure of the classification system contribute to reported comorbidity rates. These factors are often extremely difficult to distinguish from the true comorbidity of disorders. A full understanding of the common factors and shared etiologies of psychiatric disorders will most likely require an understanding of their true comorbidity. It is likely, then, that this will remain a highly controversial topic in psychopathology assessment.

3.08.4.3 Clinical and Research Applications of Classification Systems

Classification serves various purposes, depending on the setting in which it is used. In clinical settings, classification is used for treatment formulation, whereas in research settings it allows researchers to formulate and communicate ideas. The *DSM-IV* taskforce has stated that the various uses of classification are usually compatible (APA, 1994, p. xv). It is not clear whether this assertion has been tested empirically, or whether steps have been taken to resolve any divergence between the various uses of classification. The goals of clinical utility and outcome of research are not inherently inconsistent, but situations may arise in which the two diverge in their application. The majority of the modifications made to recent versions of the *DSM* were designed to improve clinical utility by simplifying or improving everyday diagnostic procedures. While not necessarily empirically driven, these changes do not appear to have adversely impacted the validity of the diagnoses they affect. Assigning diagnoses facilitates information storage and retrieval for both researchers and clinicians (Blashfield & Draguns; 1976; Mayr, 1981). However, problematic issues have been raised about the use and structure of diagnostic systems in both clinical and research settings.

The use of classification and the reliance on the *DSM* appears to be increasing (Follette, 1996). This is partly because of the trend toward the development and empirical examination of treatments geared toward specific diagnoses (Wilson, 1996). Although the use of diagnostic classification is beneficial in conceptualizing cases, formulating treatment plans, and communicating with other providers, some have argued that assigning a diagnosis may have a negative impact on patients (Szasz, 1960), that is, decisions about what constitutes pathology as opposed to normal reactions to stressors may be arbitrary (Frances, First, & Pincus, 1995), gender-based, and culturally or socioeconomically based. Furthermore, the choice of which behaviors are considered pathological (de Fundia, Draguns, & Phillips, 1971) may be influenced by the characteristics of the client (Broverman, Broverman, Clarkson, Rusenkrantz, & Vogel, 1970; Gove, 1980; Hamilton, Rothbart, & Dawes, 1986).

Diagnostic categories may also have adverse consequences on research. For example, although the diagnostic categories defined by the classifications systems are well studied and easily compared across investigations, patients who do not clearly fit a diagnosis are ignored. Furthermore, frequent and generally clinically-driven changes in the diagnostic criteria for a particular disorder make sustained investigation of the disorder difficult (Davidson & Foa, 1991). This situation is further exacerbated by the frequent addition of new diagnostic categories to the *DSM* (Blashfield, 1991). The *DSM-IV* taskforce addressed this issue by explicitly recommending that the diagnostic classifications be used as a "guideline informed by clinical judgment," as they "are not meant to be used in a cookbook fashion" (APA, 1994, p. xxiii). This suggestion, while useful in a clinical setting, may not be as applicable in research settings.

The proliferation of diagnostic criteria in recent versions of the *DSM* have successfully improved diagnostic reliability, but have done so at the expense of external validity (Clementz & Iacono, 1990). That may adversely affect research findings (Carey & Gottesman, 1978; Meehl, 1986). According to Clementz and Iacono (1990), the achievement of high reliability in a diagnostic classification is often taken to signify either validity or a necessary first step toward demonstrating validity. However, this is not the case in situations in which disorder criteria are designed significantly to increase reliability (i.e., by using a very restrictive definition). In such situations, validity may actually suffer greatly due to the increase in false categorizations of truly disordered people as unaffected. Conversely, the generation of specific behavioral criteria (e.g., Antisocial Personality Disorder in *DSM-III-R*) may increase reliability but lead to overinclusion (e.g., criminals in the antisocial category) while entirely missing other groups (e.g., "successful" psychopaths who have avoided legal repercussions of the behavior) (Lykken, 1984).

Clearly there are possible negative impacts of our current diagnostic system for research. More broadly, some have argued that nosological questions involve "value judgments" (Kendler, 1990, p. 971) and as such are nonempirical. But, as Follette and Houts (1996) point out, the classification of pathology, even in physical medicine, requires the identification of desirable endstates which are culturally rather than biologically defined. Furthermore, value judgments lie in the choices made between competing theories (Widiger & Trull, 1993) and the attempt by the authors of the *DSM* to remain theoretically "neutral" is inherently problematic. In its attempt to remain "neutral," the DSM actually adopts a model of shared phenomenology, which implicitly accepts a theory of the underlying structure of psychopathology (Follette & Houts, 1996). This implicit theory is problematic on several related fronts. First, the *DSM* professes to be theory-neutral while it may arguably be considered theory-bound. Second, because the authors of the *DSM* do not explicitly recognize any theory, specific theories cannot be empirically tested against competing theories of psychopathology.

3.08.4.4 Organizational Problems in the *DSM*

Several of the issues regarding assessment and classification revolve around the organization of the *DSM*. These problems can be classified into two broad categories: problems with the multiaxial system and problems concerning the placement and utilization of specific categories of disorders (Clark et al., 1995).

The multiaxial system of the *DSM* has no doubt accomplished its goal of increasing the attention given to various (e.g., personality) aspects of functioning. However, the distinction between certain personality (Axis II) disorders and some Axis I disorders are problematic. For example, there is now ample data suggesting that there is a high degree of overlap between avoidant personality disorder and generalized social phobia (Herbert, Hope, & Bellack, 1992; Widiger, 1992). Similarly, it is difficult to distinguish schizotypal personality disorder and schizophrenia on empirical grounds (Grove et al., 1991).

The second type of organizational issue relates to the placement and utilization of individual disorders. For example, because post-traumatic stress disorder (PTSD) shares many features (e.g., depersonalization, detachment) with the dissociative disorders, some (e.g., Davidson & Foa, 1991) have argued for its placement with the dissociative disorders instead of the anxiety disorders. Likewise, the overly exclusive diagnostic categories of the *DSM* have led to situations in which clearly disordered patients exhibiting symptoms of several disorders do not fit into any specific category. The authors of the *DSM* have attempted to remedy this by creating "not otherwise specified" (NOS) categories for several classes of disorders. While at times it is difficult to distinguish the meaning of NOS categories, they are often utilized in clinical practice. Clark et al (1995) view the high prevalence of subthreshold and atypical forms of the disorders commonly classified as NOS as contributing to the problem of heterogeneity. For example, various diagnoses including mood disorders (Mezzich, Fabrega, Coffman, & Haley, 1989), dissociative disorders (Spiegel & Cardena, 1991), and personality disorders (Morey, 1992) are characterized by high rates of NOS. One method of combating the high NOS rates would be to create separate categories to accommodate these individuals. For example, the rate of bipolar disorder NOS was reduced by the inclusion of the subcategories I and II in *DSM-IV*. Another method addressing the NOS problems is to include clear examples of individuals who would meet the NOS criteria. This second approach has been tested for some potential diagnostic groups, such as the mixed anxiety-depression category (Clark & Watson, 1991; Zinbarg & Barlow, 1991; Zinbarg et al., 1994).

3.08.5 ALTERNATIVE APPROACHES TO CLASSIFICATION

While many well-articulated criticisms of the classification system have been presented, the literature contains far fewer suggested alternatives (Follette, 1996). There is great disagreement among authors who have suggested other taxonomic models about not only the type of model, but also its content, structure, and methodology. The study of psychopathology has been pursued by researchers from different theoretical schools, including behaviorists, neurochemists, phenomenologists, and psychodynamicists (Millon, 1991). These approaches rely on unique methodologies and produce data regarding different aspects of psychopathology. No one conceptualization encompasses the complexity of any given disorder. These differing views are not reducible to a hierarchy, and cannot be compared in terms of their objective value (Millon, 1991). Biophysical, phenomenological, ecological, developmental, genetic, and behavioral observations have all been suggested as important contents to include in the categorization of psychopathology. How to structure or organize content has also been a topic of much debate. In this section the structural and methodological approaches to creating classification systems will be reviewed. Models of psychopathology will be discussed, including the Neo-Kraepelinian model, prototype models, and dimensional and categorical models. Finally, the use of etiological factors in the categorization of psychopathology (J. F. Kihlstrom, personal communication, September 2, 1997, SSCPnet) will be examined and other research and statistical methodologies will be outlined that may potentially lead to better systems of classification (J. F. Kihlstrom, personal communication, September 11, 1997, SSCPnet; D. Klein, personal communication, September 2, 1997, SSCPnet).

3.08.5.1 Types of Taxonomies

As knowledge about features best signifying various disorders increases, determinations must be made about the structure that best suits their classification. Before undertaking an investigation of the specific psychopathology classifications which have been proposed, the structural design of diagnostic taxonomies in general will be outlined briefly. The frameworks suggested fall into three categories: hierarchical, multiaxial, and circular. The hierarchical model organizes disorders into sets with higher-order diagnoses subsuming lower-order classifications. The multiaxial model assigns parallel roles for the different aspects of a disorder. Finally, the circular model assigns similar disorders to adjoining segments of a circle and dissimilar disorders to opposite sides of the circle (Millon, 1991). These three conceptualizations are not mutually exclusive, and many taxonomies share aspects of more than one structure. Within each of these three general frameworks, taxa may be considered categorical or dimensional. The current *DSM* combines both hierarchical and multiaxial approaches. Circular frameworks, which generally employ the dimensional approach, have been used in theories of personality. The model that is the basis for the *DSM* system, the Neo-Kraepelian model will be examined first, and then prototype and dimensional models will be considered Finally, suggested methodological and statistical approaches to improving the classification of psychopathology will be covered.

3.08.5.2 Taxonomic Models

3.08.5.2.1 Neo-Kraepelinian (DSM) *model*

The Neo-Kraepelinian model, inspired by the 1972 work of the Washington University group and embodied in the recent versions of the *DSM*, is the current standard of psychopathology classification. According to the Neo-Kraepelinian view, diagnostic categories represent medical diseases, and each diagnosis is considered to be a discrete entity. Each of the discrete diagnostic categories is viewed as having a describable etiology, course, and pattern of occurrence. Clearly specified operational criteria are used to define each category and foster objectivity. This type of classification is aided by the use of structured interviews in gathering relevant symptom information to assign diagnoses. Diagnostic algorithms specify the objective rules for combining symptoms and reaching a diagnosis (Blashfield, 1991). In this view, the establishment of the reliability of diagnostic categories is considered necessary before any type of validity can be established. Categories that refer to clearly described patterns of symptoms are considered to have good internal validity, while the utility of a diagnosis in predicting the course and treatment response of the disorder are seen as markers of good external validity. Despite its many shortcomings, the widespread adoption of the *DSM* system in both clinical work and research is a testament to the utility of the Neo-Kraepelinian model.

3.08.5.2.2 Prototype model

The prototype model has been suggested as a viable alternative to the current Neo-Kraepelinian approach (Cantor, Smith, French, & Mezzich, 1980; Clarkin, Widiger, Frances, Hurt, & Gilmore, 1983; Horowitz, Post, French, Wallis, & Siegelman, 1981; Livesley, 1985a, 1985b). In this system, patients' symptoms are evaluated in terms of their correlation with a standard or prototypical representation of specific disorders. A prototype consists of the most common features of members of a category, and is the standard against which patients are evaluated (Horowitz et al., 1981).

The prototype model differs from the Neo-Kraepelinian model in several ways. First, the prototype model is based on a philosophy of nominalism, in which diagnostic categories represent concepts used by mental health professionals (Blashfield, 1991). Diagnostic groups are not viewed as discrete, but individuals may warrant membership in a category to a greater or lesser degree. The categories are defined by exemplars, or prototypes, and the presentation of features or symptoms in an individual is neither necessary nor sufficient to determine membership in a category. Rather, the prototype model holds that membership in a category is correlated with the number of representative symptoms the patient has. The prototype model suggests that the degree of membership to a category is correlated with the number of features that a member has, so defining features are neither necessary nor sufficient.

Some authors have described the *DSM* system as a prototype model, primarily because it uses polythetic, as opposed to monothetic, definitions (Clarkin et al., 1983; Widiger & Frances, 1985). Although the *DSM* does use polythetic definitions, it does not constitute a prototypical model because specific subsets of symptoms are sufficient for making a diagnosis. Prototype and polythetic models allow variability among features within a category, however, they view category definition differently. Prototype models focus on definition by example, polythetic models focus on category membership as achieved by the presence of certain features that are sufficient. In a prototype model the level of membership is correlated with number of features present, and features are neither necessary nor sufficient since membership is not an absolute. Furthermore, categories in the prototype model have indistinct boundaries, and the membership decision relies largely on clinician judgment. It is likely that the adoption of this model would result in a decrease in reliability compared to the *DSM*. However, proponents argue that this model is more reflective of real-world categories in psychopathology (Chapman & Chapman, 1969).

3.08.5.2.3 Dimensional and categorical models

An alternative to the categorical classification system is the dimensional approach. In dimensional models of psychopathology, symptoms are assessed along several continua, according to their severity. Several dimensional models have been suggested (Eysenck, 1970; Russell, 1980; Tellegen, 1985). Dimensional models are proposed as a means of increasing the empirical parsimony of the diagnostic system. The personality disorders may be most readily adapted to this approach (McReynolds, 1989; Widiger, Trull, Hurt, Clarkin, & Frances, 1987; Wiggins, 1982) but this approach is by no means limited to personality disorders and has been suggested for use in disorders including schizophrenia (Andreasen and Carpenter, 1993), somatoform disorder (Katon et al., 1991), bipolar disorder (Blacker & Tsuang, 1992), childhood disorders (Quay et al., 1987), and obsessive-compulsive disorder (Hollander, 1993). Dimensional models are more agnostic (i.e., making fewer assumptions), more parsimonious (i.e., possibly reducing the approximately 300 diagnosis classifications in the *DSM* to a smaller subset of dimensions), more sensitive to differences in the severity of disorders across individuals, and less restrictive.

While a dimensional approach might simplify some aspects of the diagnostic process, it would undoubtedly create new problems. First, categorical models are resilient because of the psychological tendency to change dimensional concepts into categorical ones (Cantor & Genero, 1986; Rosch, 1978). Second, implementation of dimensional systems would require a major overhaul of current practice in the mental health field. Third, replacing the *DSM* categorical model with a dimensional model will undoubtedly meet with much resistance from proponents of clinical descriptiveness, who believe that each separate category provides a more richly textured picture of the disorder. Finally, there are currently no agreed upon dimensions to be included in such a classification model (Millon, 1991).

Thus, the task of advocates of the dimensional approach is twofold. First, they must determine the type and number of dimensions that are necessary to describe psychopathology. Second, they will need to demonstrate that it is possible to describe the entire range of psychopathology using a single set of dimensions. At this stage, the most useful starting point may be examination of the role of various dimensions in the description of psychopathology, as opposed to arguing the virtues and limitations of categorical and dimensional approaches to psychopathology.

3.08.5.3 The Use of Etiological Factors for Diagnosis

Another proposed remedy to the problems facing current classification systems is to examine the role of etiology. Andreasen and Carpenter (1993) point out the need to identify etiologic mechanisms in order to understand a disorder. In addition, understanding etiologic factors may help explain the heterogeneity and comorbidity of the disorders currently listed in the *DSM*. The authors of the *DSM* have generally avoided making statements regarding the etiology of disorders in keeping with the "theoretically neutral" stance. However, some authors have argued that this caveat is only loosely enforced in *DSM* as it is, as exemplified by life-stress based disorders such as PTSD and adjustment disorder (Brett, 1993).

Traditional models of etiology have focused on either the biological or environmental causes of psychopathology. Wakefield (1997b) has warned against the assumption that the etiology of psychopathological disorders will necessarily be found to be a physiological malfunction. He argued that the mind can begin to function abnormally without a corresponding brain disorder. More recent conceptualizations of the etiology of psychopathology acknowledge the role of both biological and environmental factors, and debate the ratio of the contribution from each. As would be expected, etiological studies of psychopathology tend to reflect the underlying theories of mental disorders accepted by the researchers who conduct them. For example, biological theorists attempt to identify biological markers of certain disorders (e.g., Clementz & Iacono, 1990; Klein, 1989). Environmental theories attempt to identify specific events that are necessary or sufficient to produce a disorder. These approaches have achieved varying degrees of success depending on which diagnostic groups were considered. One explanation for the limited success of attempts to identify etiological factors in psychopathology is the limited number of techniques available for the examination of potential factors. For example, the history of psychiatry and medicine is replete with examples of major findings due in part to advances in technology (e.g., computerized axial tomography [CAT] scans as a method of examining the function of internal organs). An alternative explanation for the limited success of etiological studies is that most researchers have relied on theoretical perspectives that assume distinct categories of illness. Specifically, the assumption of distinct diagnostic entities masks the possibility that multiple etiological factors may lead to the development of the same disorder, and that biological and environmental factors may ameliorate the effect of strong etiological factors. Even when a diagnosis may seem to have a clear etiology (e.g., PTSD), the picture is not clear. For example, although the diagnosis of PTSD requires a clear stressor it is known that not all individuals who experience that stressor develop PTSD and not all stressors are likely to create PTSD (Foa & Rothbaum, 1998). Furthermore, the presence of a stressor alone is not sufficient to warrant the diagnosis. In fact, research suggests that etiologic factors entirely outside the diagnostic criteria (e.g., IQ; Macklin et al., 1998; McNally & Shin, 1995) may ameliorate the effects of the identified etiologic factors on the development of the disorder.

Much of the controversy about assessment and classification in psychopathology stems from the conflict about the use of value judgments as opposed to data-driven theory testing in creating diagnostic categories. Some have suggested that a combination of the two perspectives, including the use of both theory and data, may be the most workable approach (Blashfield & Livesley, 1991; Morey, 1991). This approach would amount to a process of construct validation depending on both theory and evaluation of the theory by data analysis. As in other areas of theory development, testability and parsimony would play a crucial role in choosing between competing theories. In the following section, the need for the adoption of new research methodologies in the field of assessment and classification of psychopathology will be considered. Next some of the areas of research which illustrate promising methods, most of which focus on identifying etiologic factors in psychopathology, will be discussed.

As mentioned earlier, researchers have called for a move away from a system of diagnosis based on superficial features (symptoms) toward diagnosis based on scientifically-based theories of underlying etiology and disease processes. This focus parallels that of medical diagnosis of physical illness. Physicians do not diagnose based on symptoms. Instead, patient reports of symptoms are seen as indicators of potential illnesses. Diagnoses are not made until specific indicators of pathology (e.g., biopsies, masses, blood draws, etc.) have been examined. The interpretation of such laboratory results requires an understanding of the differences between normal and abnormal functioning of the cell or organ in question. In order for assessment of psychopathology to follow this route, researchers must continue to amass information on normal mental and behavioral functioning (J. F. Kihlstrom, personal communication, September 11, 1997, SSCPnet). This endeavor can be facilitated by technological advances in experimental paradigms and measurement techniques and devices. The issue of what constitutes a great enough deviation from "normal" functioning to warrant treatment has been and most likely will continue to be controversial. However, such decisions are a necessary hurdle if psychopathology is to evolve as a science.

It is likely that the identification of etiological factors in psychopathology will not rely entirely on biological factors. The validation of etiological constructs in psychopathology will undoubtedly include studies designed to identify potential contributing causes including environmental, personality, and physiological factors. Examples of research methods and paradigms which may prove useful in determining the etiology of psychiatric disorders are becoming increasingly evident in the literature. Possible methodologies include: psychopharmacological efficacy studies (Harrison et al., 1984; Hudson & Pope, 1990; Papp et al., 1993; Quitkin et al., 1993; Stein, Hollander, & Klein, 1994); family and DNA studies (Fyer et al., 1996); treatment response studies (Clark et al., 1995, Millon, 1991); *in vivo* monitoring of physiological processes (Martinez et al., 1996); and identification of abnormal physiological processes (Klein, 1993, 1994; Pine et al., 1994). These approaches may prove informative in designing future versions of psychopathology classification systems. Other researchers have chosen a more direct approach, as is evidenced in a series of articles in a special section of the *Journal of Consulting and Clinical Psychology* (*JCCP*) entitled "Development of theoretically coherent alternatives to the *DSM-IV*" (Follette, 1996). The authors of this special issue of *JCCP* pose radical alternatives to the *DSM*. The alternative classification systems are proposed from a clearly stated behavioral theoretical viewpoint, which differs considerably from many of the more biologically-based approaches described above.

A number of the alternatives and improvements suggested in the 1996 *JCCP* are based on functional analysis, the identification of the antecedents, and consequences of each behaviors (Hayes, Wilson, Gifford, Follette, & Strosahl, 1996; Scotti, Morris, McNeil, & Hawkins, 1996; Wulfert, Greenway, & Dougher, 1996). Wulfert et al. (1996) use the example of depression as a disorder which may be caused by a host of different factors (biological, cognitive, social skills deficits, or a lack of reinforcement). They argue that the fact that functionally similar behavior patterns may have very different structures may contribute to the heterogeneity found in the presumably homogenous *DSM* categories. These authors contend that functional analysis may constitute one means of identifying homogenous subgroups whose behavior share similar antecedents and consequences. This approach could be used to refine the existing *DSM* categories, and to inform treatment strategies. Hayes et al. (1996) describe a classification system based on functional analysis as a fundamentally different alternative to the current syndromal classification system. They proposed that a classification system could be based on dimensions derived from the combined results of multiple functional analyses tied to the same dimension. Each dimension would then be associated with specific assessment methods and therapy recommendations. The authors describe one such functional dimension, "experiential avoidance," and illustrate its utility across disorders such as substance abuse, obsessive-compulsive disorder, panic disorder, and borderline personality disorder (Hayes et al.). This model provides an alternative to the current *DSM* syndromal model, using the methodological approach of functional analysis. Scotti et al. (1996) proposed a similar system of categorization of childhood and adolescent disorders utilizing functional analysis. Hayes et al. (1996), Scotti et al. (1996), and Wulfert et al. (1996) have all successfully illustrated that alternatives or improvements to the current *DSM* system are possible.

However, functional analysis is a distinctly behavioral approach which assumes that a learned stimulus–response connection is an important element in the development or maintenance of psychopathology. Other authors, for example, proponents of genetic or biological explanations of psychopathology described above, might strongly oppose a classification system based purely on the methodology and tenets of a behavioral approach. Others disagree with the notion of any unified system of classification of psychopathology, arguing that no one diagnostic system will be equally useful for all of the classes of disorders now included in the *DSM* (e.g., what works for Axis I may not apply to the personality or childhood disorders). Several of these authors have taken a more radical stance, asserting the need for separate diagnostic systems for different classes of disorder (Kazdin & Kagan, 1994; Koerner, Kohlenberg, & Parker, 1996).

3.08.6 CONCLUSIONS

The assessment and classification of psychopathology is relatively new and controversies abound. However, the heated debates regarding issues such as comorbidity, types of taxonomies, and alternative approaches are indicators of the strong interest in this area. Comparisons between the classification of psychopathology and taxonomies in the basic sciences and medicine can be informative. However, the classification of psychopathology is a difficult task, and the methods used in other fields are not always applicable. It is likely that the systems of classification, informed by the continuing debates and research on the topic, will continue to evolve at a rapid pace. As Clark et al. (1995) remarked, the science of classification has inspired research in new directions and helped to guide future developments of psychopathology.

ACKNOWLEDGMENTS

We would like to thank Amy Przeworski and Melinda Freshman for their help in editing this chapter.

3.09.1 INTRODUCTION

Psychotherapy research can progress only if the treatments that are investigated can be replicated by each of the therapists within the study, and the therapy can be described to the consumers of the research results. Standards of psychotherapy research have reached a point that one cannot communicate about results without a written manual describing the treatment and methods for demonstrating therapists' adherence and competence in the delivery of the treatment. In the recent history of psychotherapy research, the manual has played a vital role in the specification of clinical trials. In addition, if a science and not just an art of psychotherapy is to flourish, there must be methods to teach clinicians how to perform the various therapies with adherence to the specific treatment strategies and techniques, and with competence in this complex interpersonal process. It is in this context that the written description of psychotherapies for specific patient populations in the form of manuals has become an essential fixture in the psychotherapy world.

There has been much lament that clinical research has little if any impact on clinical practice (Talley, Strupp, & Butler, 1994). Researchers complain that their findings are ignored. Clinicians argue that the research on rarified samples yield findings that are detailed, tedious, and irrelevant to their heterogeneous patients. It may be that the psychotherapy treatment manuals will provide a bridge between clinical research and clinical practice. The treatment manual is an accessible yield of clinical research that the clinician may find helpful, if not necessary as health delivery systems change.

This chapter draws upon various sources to describe the contents of the psychotherapy manual, provides some examples of the therapy manual movement, and discusses the advantages and disadvantages of this technology both for research and the instruction of therapists. It is interesting that, although medication management is a social process between patient and physician, with many similarities to psychotherapy, there has been little development of manuals for medication management. The informative exception is the medication management manual used in the multisite treatment study of depression (Elkin et al., 1989). Despite the fact that medication adherence is often variable and generally poor, and that there is great variation in physician behavior in dispensing medications, this area has attracted little attention, apparently because researchers and clinicians assume that providing medication is a simple and standardized behavior. We suspect this assumption is false, and that more sophisticated medication and medication–psychotherapy studies in the future will have manuals with validity checks on both psychotherapy and medication management.

3.09.2 AIMS AND INGREDIENTS OF A TREATMENT MANUAL

The concept of a treatment manual has quickly evolved in the research and clinical communities. The treatment manual was acclaimed (Luborsky & DeRubeis, 1984) as a quantum leap forward which introduced a new era in clinical research. Since that time there has been the development of numerous treatment manuals. There are even special series geared around treatment manuals, and at times accompanying materials for patients as well. In addition, the intellectual community is moving forward in defining what should be included in a treatment manual to meet standards for treatment development.

An example of the development of standards for treatment manuals is the National Institute on Drug Abuse (NIDA, Moras, 1995). The experts on this panel suggested that the aims of a treatment manual are to:

(i) make the therapy reproducible by therapists other than the immediate research group;

(ii) include information on those issues the investigator thinks are important determinants of therapy response;

(iii) delineate the knowledge base and skills needed by a therapist to learn from the manual.

Given these aims, the group suggested the following content for the manual:

(i) theory and principles of the treatment (theory underpinning the therapy, decision rules and principles to guide the therapists, information on the therapy that therapists should have to help them adopt the requisite attitude about it, i.e., belief in the treatment);

(ii) elements of the treatment (therapists, primary interpersonal stance in relation to the patient, common and unique elements of therapy);

(iii) intervention strategies for handling problems commonly encountered in delivering the therapy (miscellaneous interventions, specification of interventions not to be used in the therapy);

(iv) companion videotapes for teaching the treatment; and

(v) criteria and method of assessing therapist competence in the treatment.

In essence, these are the criteria by which one can judge the adequacy of any treatment manual.

These criteria are used to assess existing treatment manuals, some of which are used as illustrations in this chapter. As noted previously (Kazdin, 1991), it seems clear that the manuals are often incomplete, as they do not reflect the complexity of treatment and the full scope of the exchanges between therapist and patient. However, the development of treatment manuals has and continues to help the field move forward.

It should be noted that there is a difference between a treatment manual and a book published and marketed that has many but not all of the attributes of a practical, ever-changing treatment manual. In an attempt to make a book of publishable size, things that might be included in the working manual, such as clinician work sheets or rating scales might be eliminated from the book. A notable exception is the work by Linehan which includes both a book (Linehan, 1993a) and an accompanying workbook (Linehan, 1993b) with therapist work sheets and other material most useful in practical delivery of the treatment. The treatment manual of the near future will probably be both a written description of the treatment in book form, and an accompanying CD-ROM that provides video demonstration of the treatment (using therapists and actor/patients).

3.09.3 DIMENSIONS ALONG WHICH THE MANUALS VARY

The existing treatment manuals can be compared not only to the content as specified by the NIDA experts, but also by differences in aspects of the treatment, including: the process by which the authors generated and elucidated their treatment; the patient population for which the treatment is intended; the knowledge base of the disorder being treated; treatment strategies and techniques, duration, and format; and level of abstraction in which the manual is written.

3.09.3.1 Process of Manual Generation and Elucidation

What was the process of manual generation by the authors? Was the manual generated from extensive experience with a patient population, followed by a codification of the techniques that seem to work on a clinical basis? Conversely, was the manual generated from a theoretical understanding of the patient population followed by treatment contact? Was it generated from a specific treatment orientation, for example, cognitive-behavioral, that is then applied to a specific patient population? Is the manual generated by clinical researchers or by clinicians? Was the manual generated during extensive clinical research, profiting from that research, or without research experience? Does the manual have accompanying aids, such as audiotapes and work sheets?

3.09.3.2 Patient Population

Therapy manuals differ in the extent to which they specify for which patients the manual is intended and for which patients the manual has not been attempted, or, indeed, for whom the treatment does not work. Since psychotherapy research funding is focused on *DSM*-diagnosed patient groups, many of the manuals describe treatments for patient groups defined by diagnosis. This fact has both positive and negative aspects. Some diagnoses are close to phenomenological descriptions of behavioral problems, so the diagnoses are immediate descriptions of problems to be solved. An example is the treatment of phobic anxiety, agoraphobia, and panic attacks. In contrast, the diagnosis of depression is more distant from specific behaviors, so the manuals describing treatments for depression have implicit theories about the nature of depression, such as the interpersonal treatment or the cognitive treatment. Linehan's manual for the treatment of parasuicidal individuals is an interesting transitional one, from a behavior (repetitive suicidal behavior) to a diagnosis that sometimes includes the behavior (borderline personality disorder). In contrast, there are manuals written not for patients with specific diagnoses but for those with certain problems such as experiencing emotions (Greenberg, Rice, & Elliott, 1993).

An additional way the manual being considered is specific to a population is the attention given to the details of patient assessment. Ideally, the assessment section would inform the reader of the patients included and excluded, and the subgroups of patients within the diagnosis/category treated by this manual, but treated with the differences in mind depending on such factors as comorbid conditions.

One difficulty that is becoming more clear is that, for those manuals that have been written for a specific disorder, how do they apply to patients with the disorder but with a common comorbid disorder? For example, the interpersonal psychotherapy manual was constructed with ambulatory, nonpsychotic patients with depression in mind, but gives little indication of its application when there are prominent Axis II disorders. Of course, this point also relates to the accumulation of knowledge that occurs all the time, so that a manual published a few years ago may need modification and updating as more data becomes available.

3.09.3.3 Knowledge Base of the Disorder

One could make a cogent argument that a treatment for a particular disorder cannot (should not) be developed until there is sufficient information on the natural course of the disorder at issue. Only with the background of the natural development of the disorder can one examine the impact of intervention. Furthermore, the age of the patients to whom the treatment is applied is most relevant in the context of the longitudinal pattern of the disorder in question. However, in light of the clinical reality of patients in pain needing intervention, the development of intervention strategies cannot wait for longitudinal investigations of the disorder. Both arguments are sound, but we can describe intervention manuals based on the natural history of the disorder versus those that do not have such a database upon which to build.

3.09.3.4 Treatment Strategies and Techniques

Obviously, treatment manuals differ in the strategies and techniques that are described. This would include manualization of treatments that use behavioral, cognitive, cognitive-behavioral, systems, supportive, and psychodynamic techniques. Less obvious is the fact that it may be easier to manualize some strategies/techniques more than others. In fact, some therapies may be more technique oriented and others relatively more interpersonally oriented, and this may have implications for the method of manualization and the results.

An issue related to strategies and techniques is the degree to which the treatment manual describes the stance of the therapist with respect to the patient, the induction of the patient into the treatment roles and responsibilities, and the development of the therapeutic relationship or alliance. Often, it is the ambivalent patient who questions the value of the treatment, is prone to drop out, or to attend therapy with little investment and involvement (e.g., does not carry out therapy homework) that provides a serious challenge to the therapist. The more complete manuals note the typical difficulties and challenges to full participation in the treatment that have been observed in experience with the patient population, and offer guidelines for the therapist in overcoming these challenges.

3.09.3.5 Treatment Duration

Most manuals describe a brief treatment of some 12–20 sessions. The methods for manualizing longer treatments may present a challenge to the field. A brief treatment can be described in a manual session by session. Each session can be anticipated in a sequence and described. This is especially true if the treatment is cognitive-behavioral in strategies and techniques, and can be anticipated as applied to the particular condition/disorder. In contrast, as the treatment becomes longer, and as the treatment deviates from a cognitive-behavioral orientation to one that depends more on the productivity and nature of the individual patient (e.g., interpersonal and psychodynamic treatment), the manual will of necessity become more principle based and reliant on what the patient brings to the situation.

3.09.3.6 Treatment Format

Psychotherapy is delivered in individual, group, marital, and family treatment formats. It would seem to be simpler, if not easier, to articulate a treatment manual for two participants (i.e., therapist and one patient), rather than a manual for therapist and many patients (i.e., family and group treatment). As the number of patients in the treatment room increases, the number of patient-supplied interactions increases, as does the potential for treatment difficulties and road blocks.

3.09.3.7 Level of Abstraction

The very term “manual” conjures up an image of the book that comes in the pocket of a new car. It tells how to operate all the gadgets in the car, and provides a guide as to when to get the car serviced. Diagrams and pictures are provided. It is a “how to” book on repair and maintenance of your new car. Thus, the term “treatment manual” promises to describe how to do the treatment in step-by-step detail.

More relevant to psychotherapy manuals are the manuals that inform the reader—often with graphs and pictures—how to sail a boat or play tennis. This is a more apt analogy because the manual attempts in written (and graphic) form to communicate how to achieve complex cognitive and motor skills. Opponents of treatment manuals will point to golfers who have read all the manuals, and hack their way around the course with less than sterling skill. (To us, this does not argue against the manual, but speaks of its limitations and how it should be used in the context of other teaching devises.)

Ignoring the critics for the moment, this discussion raises the issue of what level of concreteness or abstraction is the manual best formulated. Some manuals describe the treatment session by session, and within the individual session the flow of the session and details about its construction are indicated. Obviously, this is easier to do the shorter the treatment, and the more the treatment can be predicted from the beginning (i.e., the more the treatment is driven by the therapist and little influenced by patient response or spontaneous contribution). Probably the best manuals are those that constantly weave abstract principles and strategies of the treatment with specific examples in the form of clinical vignettes that provide illustrations of the application of the principles to the individual situation.

3.09.4 RANGE OF TREATMENT MANUALS

An exhaustive list of existing treatment manuals cannot be provided for many reasons, not the least of which is that the list would be out of date before this chapter goes to print. The American Psychological Association (APA), Division 12, Task Force on Psychological

Interventions lists the so-called efficacious treatments (Chambless et al., 1998) and has also listed treatment manuals that are relevant to the efficacious treatments (Woody & Sanderson, 1998). Some 33 treatment manuals are listed for 13 disorders and/or problem areas including bulimia, chronic headache, pain associated with rheumatic disease, stress, depression, discordant couples, enuresis, generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, social phobia, specific phobia, and children with oppositional behavior. Not all of the manuals listed here have been published, and must be sent for to the originator. Further, this list is limited to only those treatments that have been judged by the Task Force of Division 12 to meet their criteria for efficaciousness.

3.09.5 REPRESENTATIVE TREATMENT MANUALS

In contrast, a listing of representative treatment manuals is provided here, using as the structure for such sampling the diagnoses in the *Diagnostic and statistical manual of mental disorders* (4th ed., *DSM-IV*).

This chapter uses three treatment manuals to illustrate the present state of the art in manualization of psychotherapy: *Interpersonal psychotherapy of depression* (IPT; Klerman, Weissman, Roundsaville, & Chevron, 1984), the dialectical behavioral treatment (DBT) for borderline personality disorder (BPD) and related self-destructive behaviors (Linehan, 1993a), and the family treatment of bipolar disorder (Miklowitz & Goldstein, 1997). One of these treatments and related treatment manuals (IPT) has achieved recognition in the APA Division 12 listing of efficacious treatments. One (DBT for BPD) is listed as a “probably efficacious treatment.” The third (family treatment for bipolar disorder) is not listed at this time. These manuals are also selected because they relate to existing *DSM* diagnostic categories which are central to research data and to insurance company procedures for reimbursement of treatment. These manuals for the specified disorders are also chosen because they represent three levels of severity of disorder that face the clinician. Ambulatory patients with depression of a nonpsychotic variety are treated with IPT. BPD is a serious disorder, often involving self-destructive and suicidal behavior. Finally, bipolar disorder is a psychiatric condition with biological and genetic causes that can be addressed by both the empirically efficacious medications and psychotherapy. In addition, these three treatment manuals provide some heterogeneity in terms of treatment format, strategies and level of treatment development. IPT is delivered in an individual treatment format (patient and individual therapist), the treatment format that is the simplest to manualize. DBT involves both an individual and a group treatment format. The family treatment of bipolar disorder involves the treatment of the individual with bipolar disorder and family or marital partner. There is less diversity among these three treatments in terms of treatment strategies and techniques. Two (DPT and family treatment of bipolar) are informed by cognitive-behavioral strategies and techniques, but the latter introduces the intriguing concepts of family dynamics and systems issues. The remaining (IPT) is interpersonal in focus and orientation. The three manuals vary in terms of treatment duration. IPT is brief, the family treatment of bipolar is intermediate, and DBT is the longest, presenting the most challenge to issues of manualization and therapist adherence across a longer period of time. A comparison of these three manuals gives a sense of development in this area, as the IPT manual was one of the first, and the latter two provide a view of recent manuals and their contents.

3.09.5.1 IPT: An Early Manual

One of the earliest and most influential manuals is *Interpersonal psychotherapy of depression* by Klerman et al. (1984). This manual was written as a time-limited, outpatient treatment for depressed individuals. The treatment focuses on the current rather than on past interpersonal situations and difficulties. While making no assumption about the origin of the symptoms, the authors connect the onset of depression with current grief, role disputes and/or transitions, and interpersonal deficits.

This brief intervention has three treatment phases which are described clearly in the manual. The first is an evaluation phase during which the patient and therapist review depressive symptoms, give the syndrome of depression a name, and induce the patient into a sick role. (Interestingly, the role of the therapist is not described explicitly.) The patient and therapist discuss and, hopefully, agree upon a treatment focus limited to four possibilities: grief, role disputes, role transitions, or interpersonal deficits. The middle phase of treatment involves work between therapist and patient on the defined area of focus. For example, with current role disputes the therapist explores with the patient the nature of the disputes and options for resolution. The final phase of treatment involves reviewing and consolidating therapeutic gains. A recent addition is the publication of a client workbook (Weissman, 1995) and client assessment forms.

IPT has been used in many clinical trials, the first of which was in 1974 (Klerman, DiMascio, Weissman, Prusoff, & Paykel, 1974). In addition to the IPT manual, a training videotape has been produced and an IPT training program is being developed (Weissman & Markowitz, 1994).

IPT provides a generic framework guiding patient and therapist to discuss current difficulties and this framework has been applied to symptom conditions other than depression. For example, the format has been applied to patients with bipolar disorder (Ehlers, Frank, & Kupfer, 1988), drug abuse (Carroll, Rounsaville, & Gawin, 1991; Rounsaville, Glazer, Wilber, Weissman, & Kleber, 1983), and bulimia (Fairburn et al., 1991). In addition to its initial use of treating depression in ambulatory adult patients, it has now been utilized as an acute treatment, as a continuation and maintenance treatment (Frank et al., 1990), and has been used for geriatric (Reynolds et al., 1992) and adolescent patients (Mufson, Moreau, Weissman, & Klerman, 1993) and in various settings such as primary care and hospitalized elderly. The success of IPT seems to be the articulation of a rather straightforward approach to discussion between patient and therapist, of current situations without the use of more complicated procedures such as transference interpretation.

The IPT manual was one of the first in the field, and its straightforward description of a common-sense approach to patients with depression is readily adopted by many clinicians. However, the process of treatment development and amplification is also relevant to this, one of the earliest and best treatment manuals. It is now clear that depression is often only partially responsive to brief treatments, such as IPT, and that many patients relapse. It would appear that maintenance treatment with IPT may be useful (Frank et al., 1991), and the IPT manual must therefore be amplified for this purpose. Furthermore, it has become clear that depressed individuals with personality disorders respond to treatment less thoroughly and more slowly than depressed individuals without personality disorders (Clarkin & Abrams, 1998). This would suggest that IPT may need modification for those with personality disorders, either in terms of how to manage the personality disorder during treatment, or to include treatment of relevant parts of the personality disorder to the depression.

In order to place IPT in perspective, one could compare it to the cognitive therapy of depression in its earliest articulation (Beck, Rush, Shaw, & Emery, 1979) and with more recent additions (Beck, 1995).

3.09.5.2 Cognitive-behavioral Treatment of BPD

Linehan's (1993a, 1993b) cognitive-behavioral treatment of the parasuicidal individual is an example of the application of a specific school of psychotherapy adapted to a specific patient population defined both by a personality disorder diagnosis (BPD) and repetitive self-destructive behavior.

The rationale and data upon which the patient pathology is understood as related to the treatment is well described and thorough. Linehan points out that theories of personality functioning/dysfunctioning are based upon world views and assumptions. The assumption behind DBT is that of dialectics. The world view of dialectics involves notions of inter-relatedness and wholeness, compatible with feminist views of psychopathology, rather than an emphasis on separation, individuation, and independence. A related principle is that of polarity, that is, all propositions contain within them their own oppositions. As related to the borderline pathology, it is assumed that within the borderline dysfunction there is also function and accuracy. Thus, in DBT, it is assumed that each individual, including the borderline clients, are capable of wisdom as related to their own life and capable of change. At the level of the relationship between borderline client and DBT therapist, dialectics refers to change by persuasion, a process involving truth not as an absolute but as an evolving, developing phenomenon.

Borderline pathology is conceptualized as a dialectical failure on the part of the client. The thinking of the BPD patient has a tendency to become paralyzed in either the thesis or antithesis, without movement toward a synthesis. There is a related dialectical theory of the development of borderline pathology. BPD is seen primarily as a dysfunction of the emotion regulation system, with contributions to this state of malfunction from both biological irregularities and interaction over time with a dysfunctional environment. In this point of view, the BPD client is prey to emotional vulnerability, that is, high sensitivity to emotional stimuli, emotional intensity, and a slow return to emotional baseline functioning. The invalidating environment, seen as crucial to the BPD development, is one in which interpersonal communication of personal and private experiences is met by others in the environment with trivialization and/or punishment. In such an environment, the developing individual does not learn to label private experiences, nor does the individual learn emotion regulation.

These assumptions and related data on the developmental histories and cross-sectional behaviors of those with BPD provide the rationale and shape of the treatment. The major tasks of the treatment are, therefore, to teach the client skills so that they can modulate emotional experiences and related mood-dependent behaviors, and to learn to trust and validate their own emotions, thoughts and activities. The relevant skills are described as four in type: skills that increase interpersonal effectiveness in conflict situations, strategies to increase self-regulation of unwanted affects, skills for tolerating emotional distress, and skills adapted from Zen meditation to enhance the ability to experience emotions and avoid emotional inhibition.

The manual provides extensive material on basic treatment strategies (e.g., dialectical strategies), core strategies of emotional validation (e.g., teaching emotion observation and labeling skills), behavioral validation (e.g., identifying, countering and accepting "shoulds"), and cognitive validation (e.g., discriminating facts from interpretations), and problem-solving strategies. Problem solving consists of analysis of behavior problems, generating alternate behavioral solutions, orientation to a solution behavior, and trial of the solution behavior. The core of the treatment is described as balancing problem-solving strategies with validation strategies.

This manual is exceptional, and provides a new and very high standard in the field for treatment manuals. There are a number of exemplary features. First, the patient population is defined by *DSM* criteria in addition to specific problematic behaviors, that is, parasuicidal behaviors. Second, the treatment manual was generated in the context of clinical research. The treatment was developed in the context of operationalization and discovery, that is, how to operationalize a treatment for research that fits the pathology of the patients who are selected and described by specific criteria. The skills training manual (Linehan, 1993b) notes that it has evolved over a 20 year period, and has been tested on over 100 clients. The treatment generated in this context has been used in diverse treatment settings to teach therapists of various levels of expertise and training to address BPD patients. This process of teaching the treatment to therapists of multiple levels of competence and training can foster the articulation of the treatment and enrich its adaptability to community settings. This treatment has a duration of one year or more because it is addressed to a very difficult and seriously disturbed group of individuals, and provides the challenge of extending treatment manuals beyond brief treatments. A most important and practical addition to the book is an accompanying workbook with work sheets for therapist and patients.

To put DBT in context one could compare it to other cognitive approaches to the personality disorders (Beck & Freeman, 1990), to an interpersonal treatment delivered in a group format (Marziali & Munroe-Blum, 1994), to a modified psychodynamic treatment (Clarkin, Yeomans, & Kernberg, in press), and to a supportive treatment (Rockland, 1992) for these patients.

3.09.5.3 Psychosocial Treatment For Bipolar Disorder

Capitalizing on their years of clinical research with patients with schizophrenia and bipolar disorder and their families, Miklowitz and Goldstein (1997) have articulated a treatment manual for patients with bipolar disorder and their spouses or family members.

The rationale for the treatment is threefold. An episode of bipolar disorder in a family member affects not only the patient but the entire family. Thus, with each episode of the disorder (and this is a recurring disorder) there is a crisis and disorganization of the entire family. Thus, the family treatment is an attempt to assist the patient and family to cooperatively deal with this chronic illness. Finally, both in the rationale for the treatment and in the psychoeducational component of the treatment, the authors espouse a vulnerability–stress model of the disorder, which would argue for a treatment that reduces patient and family stress.

The therapeutic stance of the clinician conducting this treatment is explicated well. The clinician is encouraged to be approachable, open and emotionally accessible. It is recommended that the clinician develop a "Socratic dialogue" with the family in providing information, and develop a give and take between all parties. Although the treatment has a major psychoeducational component, the clinician is encouraged to be ready to explore the emotional impact of the information, and not to be simply a classroom teacher. In dealing with both difficult news (e.g., you have a life-long illness) and tasks (e.g., problem solving helps reduce stress), the clinician is encouraged to be reasonably optimistic about what the patient and family can accomplish if they give the treatment and its methods a chance to succeed.

The treatment is described in the manual in terms of three major phases or modules that have a clear sequence to them. The first phase of psychoeducation is intended to provide the patient and family with information that gives them an understanding of bipolar disorder and its treatment. It is hoped that this information may have practical value in informing the patient and family as to things they should do (e.g., medication compliance) that assists in managing the illness. The second phase or module of treatment is a communication enhancement training phase. The aim of this phase is to improve and/or enhance the patient and family's ability to communicate with one another clearly and effectively, especially in the face of the stress-producing disorder. The third or problem-solving phase provides the patient and family with training in effective conflict resolution. Prior to extensive explanation of the three phases of the treatment is information on connecting and engaging with patient and family, and conducting initial assessment. The authors also examine carefully patient and family criteria for admission to this family intervention. Interestingly, they do not rule out patients who are not medication compliant at present, nor those who are currently abusing substances, both common situations in the history of many bipolar patients. This is an articulated treatment broad enough to encourage those patients who are on the cusp of what is actually treatable.

This manual raises directly the issue of patient medication compliance and the combination of psychosocial treatment with medication treatment. Bipolar patients are responsive to certain medications, and medication treatment is considered a necessity. Thus, this treatment manual provides psychoeducation around the need for medication, and encourages patient and family agreement about continuous medication compliance.

This treatment manual can be placed in context by comparing it to a treatment for bipolar disorder in the individual treatment format (Basco & Rush, 1996). This manual should also be seen in the context of quite similar treatments for patients with schizophrenia and their families (such as those articulated by Anderson, Reiss, & Hogarty, 1986; Bellack, Mueser, Gingerich, & Agresta, 1997; Falloon, Boyd, & McGill, 1984).

3.09.5.4 Other Treatment Manuals

Beyond the three manuals chosen for illustration, it is interesting to note the patient diagnoses and problem areas that are currently addressed by a manual describing a psychotherapy. As noted in Table 1, there are treatments described in manuals for major Axis I disorders such as schizophrenia, bipolar disorder, major depression, anxiety disorders, substance abuse and eating disorders. Treatments for Axis II disorders are less well developed and manualized, except for BPD. Problem areas such as marital discord, sexual dysfunction and problematic emotion expression are also addressed. Further development will probably come in addressing common comorbid conditions. In addition, there has been more funding and research for brief treatments with a cognitive-behavioral orientation. Longer treatments, maintenance treatment for chronic conditions, and the development of manuals for strategies and techniques other than cognitive-behavioral ones can be expected in the future. With the heavy incursion of managed care with its emphasis on cost-cutting, more development of treatments delivered in a group format may also be seen.

3.09.6 ADVANTAGES OF TREATMENT MANUALS

It is clear that the introduction of the treatment manual has had tremendous impact. The very process of writing a treatment manual forces the author to think through and articulate the details of the treatment that may not have been specified before. In this way, the era of the written treatment manual has fostered fuller articulation of treatment by the treatment originators, and furthered the ability of teachers of the treatment to explicate the treatment to trainees.

Manuals provide an operationalized statement of the treatment being delivered or researched so that all can examine it for its foci and procedures. It cannot be assumed that the treatment described in the written manual was delivered as described by the therapists in the study or in a treatment delivery system. This gap between the manual and the treatment as delivered highlights the need for rating scales to assess the faithful (i.e., adherent and competent) delivery of the treatment as described in the manual.

Manuals provide a training tool for clinical research and for clinical practice. It has been noted (Chambless, 1996; Moras, 1993) that students learn treatment approaches much more quickly from their systematic depiction in manuals than through supervision alone.

3.09.7 POTENTIAL DISADVANTAGES AND LIMITATIONS OF TREATMENT MANUALS

Dobson and Shaw (1988) have noted six disadvantages of treatment manuals: (i) the

Table 1 Representative treatment manuals.

Disorder/problem area	*Reference*
Panic	Barlow and Cerny (1988)
Obsessive-compulsive disorder	Steketee (1993) Turner and Beidel (1988)
PTSD	Foy (1992)
Depression	Beck, Rush, Shaw, and Emery (1979) Klerman, Weissman, Rounsaville, and Chevron (1984)
Bipolar	Miklowitz and Goldstein (1997) Basco and Rush (1996)
Schizophrenia	Bellack (1997) Anderson, Reiss, and Hogarty (1986) Falloon, Boyd, and McGill (1984)
Borderline	Linehan (1993a, 1993b) Clarkin, Yeomans, and Kernberg (in press) Marzialli and Munroe-Blum (1994) Rockland (1992)
Marital discord	Baucom and Epstein (1990)
Sexual dysfunction	Wincze and Carey (1991)
Alcohol abuse	Sobell and Sobell (1993)
Binge eating	Fairburn, Marcus, and Wilson (1993)
Problematic emotion schemas	Greenberg, Rice, and Elliott (1993)

inability to assess the effects of therapists' variables, (ii) the diminished ability to study the therapy process, (iii) a focus on treatment fidelity rather than on competence, (iv) the increased expense for research, (v) the over-researching of older and more codified therapy procedures; and (vi) the promotion of schools of psychotherapy. It is important to distinguish the limitations of the manuals as they have been developed up to now, from the limitations of manuals as they can be if the field continues to improve them. There is no reason why many of the concerns listed above cannot be incorporated into future manuals. Some are already being included, such as therapist variables, process, and competence.

Probably the most extensively debated issue around manuals is the issue of therapist flexibility in the execution of the treatment. Some would argue that a manual seriously curtails the flexibility and creativity of the therapist, thus potentially eliminating the therapeutic effectiveness of talented therapists. This is the type of issue that, unless infused with data, could be debated intensely for a very long time. Jacobson et al. (1989) compared two versions of behavioral marital therapy, one inflexible and the other in which therapists had flexibility. The outcome of the flexibility condition was no better than that of the inflexible condition. There was a trend for less relapse at follow-up in the flexibly treated couples.

Wilson (1996) notes that allowing therapists to pursue their own somewhat ideographic case formulations rather than following validated treatment in manuals on average might reduce effectiveness rather than enhance it (Schulte, Kuenzel, Pepping, & Schulte-Bahrenberg, 1992). When research therapy programs are transferred to a clinic setting, there tends to be an increase in effectiveness (Weisz, Donenberg, Han, & Weiss, 1995). A number of studies show that greater adherence to the psychotherapy protocol predicts better outcome (Frank et al., 1991; Luborsky, McLellan, Woody, O'Brien, & Auerbach, 1985).

However, it has been pointed out that adherence to manualized treatments may lead to certain disruptive therapists' behaviors (Henry, Schacht, Strupp, Butler, & Binder, 1993). There is the possibility that therapists delivering a manualized treatment, especially those that are just learning the treatment and adhering with concentration, will deliver it with strict adherence but without competence. At its extreme, it might be argued that the use of the treatment manual may de-skill the therapist and interfere with therapist competence. In fact, rigid adherence could lead to poor therapy, and a mockery of what the treatment is intended to be.

In a study reported by Castonguay, Goldfried, Wiser, Raue, and Hayes (1996), when therapists were engaged in an abstract cognitive intervention the outcome appeared worse. However, those interventions were related to a bad outcome only when practiced to the detriment of the therapeutic alliance.

Jacobson and Hollon (1996) point out that the measurement of therapist adherence to treatments as manualized has received much attention, but the measurement of competence is at a rudimentary stage. The manual should provide instruments that have been shown to reliably assess therapist adherence to the treatment as described in the manual, and competence in the delivery of that treatment. Many books that proport to be treatment manuals do not include such instrumentation. The instruments are helpful in further specifying necessary therapist behaviors, and may be useful to the clinical supervisor.

A major limitation of manual development is the number of patients who appear for treatment who are not addressed in the existing treatment manuals. Some of this is due to the research focus of manuals, that is, the need for clinical research to have a narrowly and carefully defined patient population for whom the treatment is intended. Unfortunately, many if not most patients who appear in clinical settings would not fit into a research protocol because of comorbidity, not quite meeting criteria for a specific diagnosis (e.g., personality disorder NOS, not otherwise specified). Some of this is simply due to the newness of manuals and the little time there has been in their development.

3.09.8 USE AND ROLE OF TREATMENT MANUALS

Treatment manuals have had a brief but exciting and productive history. There is an extreme position that something as complex, unique and creative as a psychotherapy between two individuals cannot be manualized. It is thought that experience indicates that this is an extreme view, and that manualization has been useful to the field. The issues are how best to utilize a manual and what is the role of the manual in clinical research and training?

Whether in the early stages of clinical research or in a clinical training program, the treatment manual can serve as a tool to be used by the expert therapist who is teaching the treatment. It has been noted that the manual enables the student to learn the treatment more quickly than with supervision alone (Chambless, 1996; Moras, 1993). It is our experience, however, that the manual has a place in the teaching toolbox, but is less important than supervision and watching experts doing the treatment on videotape. The manual provides a conceptual overview of the treatment. Videotapes provide a visual demonstration of the manual being applied to a particular patient, in the style of a particular therapist model. Supervision allows the expert to help the trainee apply the manual to a specific patient in a specific treatment, which will always produce some situations that are not exactly covered in the written manual.

It is a naive and false assumption that a clinician can simply read a treatment manual, and thereby be enabled to deliver the treatment with skill. It is interesting that the authors of a treatment manual (Turner & Beidel, 1988) felt the need to argue that just reading a manual is not enough to train an individual in the competent delivery of the treatment in question to the individual patient.

3.09.8.1 Efficacy to Effectiveness

There is currently much discussion about the need to extend clinical trials of empirically validated treatments, that is treatments that have been shown to be efficacious, to larger, community samples with average therapists (effectiveness research). It may be that treatment manuals can play an important role in this work. Indeed, the ultimate value of a treatment manual and the training system within which it operates will be the result that clinicians can perform the treatment with adherence and competence. Manuals that are most useful will contain scales developed to measure therapist adherence and competence, and most current manuals are lacking this feature.

3.09.9 SUMMARY

Although treatment manuals have been effective in specifying psychotherapy for clinical research, the step from clinical efficacy studies to demonstration of clinical effectiveness of the treatments that have been manualized is still lacking. This is an issue of knowledge transfer. That is, given the demonstration that a specific therapy (that has been manualized) has shown clinical efficacy in randomized clinical trials with a homogeneous patient population and with carefully selected therapists, can this treatment also show clinical benefits when transferred to a setting in which the patients are less homogeneous and the therapists are those who are working at the local level? The written treatment manual may play a role in this transfer of expertise from a small, clinical research group to a larger group of therapists. However, this step has yet to be demonstrated. Thus, the test of a manual, and the entire teaching package within which it resides, is to demonstrate that a wider group of therapists can do the treatment with adherence and competence.

It is interesting to speculate about the future of training in psychotherapy given the advances in the field, including the generation of treatment manuals. For sake of argument, we indicated that there are some 33 manuals for 13 disorders for which there are efficacious treatments in the field of clinical psychology. Should these manuals form the basis of the training in psychotherapy of future psychologists? Or can one generate principles of treatment out of these disparate treatments for various disorders and conditions, and teach these principles? There are obvious redundancies across the manuals, and one could imagine a supermanual with branching points for various disorders. For example, most manuals have an assessment phase, followed by the phase of making an alliance with the patient and describing the characteristics of the treatment to follow, with some indication of the roles of patient and therapist. These are obvious skills that a therapist must learn, with nuances depending upon the patient and the disorder in question. For those manuals that are cognitive behavioral in strategies and techniques, there seems to be great redundancy in terms of the selected finite number of techniques that are used.

What is missing is the assessment of the patient in which there is no indication of what the problem is, the diagnosis, or which manual or manuals to use for treatment. Each manual seems to presume that clinicians can properly identify patients for that manual. Unfortunately, one cannot train a psychologist to treat only the 13 disorders/problem areas in the list, as many patients suffer from other conditions not covered. To compound things even further, many patients (if not most, depending on the clinical setting) do not suffer from just one condition, but from several.

Our own approach to training is the one implied by Roth, Fonagy, Parry, Target, and Woods (1996), with emphasis on the initial assessment of the patient with specific clinical hypotheses about the situation, proceeding to the most relevant treatment that has been validated to various degrees. This is a less black-and-white world of the empirically supported treatment approach and more related to the complex condition we call clinical work. Treatment manuals will play some role in this process, but it might be less than the quantum leap suggested by Luborsky and DeRubeis (1984). In our experience, trainees read the treatment manual if they must, but they look forward to seeing experts do the treatment on videotape, and they see supervision from an expert in the treatment as a matter of course.

3.10.1 INTRODUCTION

The concepts of internal and external validity (IV and EV) were introduced by Campbell and Stanley in 1963. IV and EV concern the validity of inferences that can be drawn from an intervention study, given its design and methods. The concepts are used to assess the extent to which a study's outcome findings can be confidently: (i) interpreted as evidence for hypothesized causal relationships between interventions and outcomes (IV), and (ii) assumed to generalize beyond the study situation (EV). IV and EV are conceptual tools that guide deductive (IV) and inductive (EV) thinking about the impact of a study's design and methods on the validity of the conclusions that can be drawn from it. The concepts are not only of academic interest. Evaluation of a study's IV and EV is a logical, systematic way to judge if its outcome findings provide compelling evidence that an intervention merits implementation in public sector settings.

This chapter is written at a unique time in the history of IV and EV. The concepts have been at the forefront of a contemporary, often contentious debate in the USA about the public health value of alternative methods and designs for intervention research (e.g., Goldfried Wolfe, 1998; Hoagwood, Hibbs, Bren, & Jensen, 1995; Jacobson & Christensen, 1996; Lebowitz & Rudorfer, 1998; Mintz, Drake, & Crits-Christoph, 1996; Newman & Tejeda, 1996; Seligman, 1996; Wells & Sturm, 1996). The alternatives are referred to as "efficacy" vs. "effectiveness" studies. In current parlance, efficacy studies have high IV due to designs and methods that reflect a priority on drawing causal conclusions about the relationship between interventions and outcomes (e.g., Elkin et al., 1989). Effectiveness studies have high EV due to designs and methods that reflect the priority of obtaining findings that can be assumed to generalize to nonresearch intervention settings and clinic populations (e.g., Speer, 1994). Typically, effectiveness studies are done to examine the effects of interventions with demonstrated efficacy in high IV studies, when the interventions are used in standard community treatment settings. A related term, "clinical utility research," has started to appear (Beutler & Howard, 1998). The types of research questions connoted by clinical utility are broader than those connoted by effectiveness research (Howard, Moras, Brill, Martinovich, & Lutz, 1996; Kopta, Howard, Lowry, & Beutler, 1994; Lueger, 1998).

The efficacy vs. effectiveness debate is prominent in mental health intervention research. IV and EV often are viewed as competing rather than complimentary research aims (Kazdin, 1994; Roth & Fonagy, 1996). An alternative view is that EV questions only can be asked about a study's findings after the study's IV has been established (Flick, 1988; Hoagwood et al., 1995). A recent trend is to encourage investigators to design studies that can optimize both IV and EV (Clarke, 1995; Hoagwood et al., 1995). The topic is pursued later in the chapter.

This chapter is intended to provide a relatively concise, simplified explication of IV and EV that will be useful to neophyte intervention researchers and to consumers of intervention research. The main aims are to enhance the reader's sophistication as consumer of intervention research, and ability to use the concepts of IV and EV to design intervention studies. IV and EV are discussed and illustrated mainly from the perspective of research on interventions of a certain type: psychological therapies for mental health problems (Bergin & Garfield, 1971, 1994; Garfield & Bergin, 1978, 1986).The topics covered are: (i) definitions of IV and EV and of two newer, closely related concepts, construct validity (CV) and statistical conclusion validity (SCV); (ii) threats to IV, EV, CV, and SCV; (iii) designs and methods that are commonly used in mental health intervention research to enhance IV, EV, CV, and SCV; and (iv) suggested strategies from the efficacy vs. effectiveness debate to optimize the scientific validity, generalizability, and public health value of intervention studies. Finally, two intervention studies that were designed to meet both IV and EV aims are used to illustrate application of the concepts.

3.10.2 DEFINITIONS

3.10.2.1 Overview of IV, EV, CV, and SCV

Kazdin (1994) provided a concise overview of IV, EV, CV, and SCV, and of common threats to each type of validity (Table 1). The discussion of the four concepts in this chapter is based on Cook and Campbell's (1979) conceptualizations, as is Kazdin's table. Campbell and Stanley's (1963, 1966) original conceptualizations of IV and EV were extended and slightly revised by Cook and Campbell in 1979. The arguments and philosophy of science assumptions that underpin Cook and Campbell's (1979) perspective have been challenged (Cronbach, 1982). A key criticism is that they overemphasized the value of high IV studies in a way that was inconsistent with EV (generalizability) trade-offs often associated with such studies (Shadish, 1995). Cook and Campbell's views were adopted in this chapter because, challenges notwithstanding, they have had a major influence on mental health intervention research since the late 1960s.

Table 1 Types of experimental validity, questions they address, and their threats to drawing valid inferences.

Type of validity	*Questions addressed*	*Threats to validity*
Internal validity	To what extent can the intervention, rather than extraneous influences, be considered to account for the results, changes, or group differences?	Changes due to influences other than the experimental conditions, such as events (history) or processes (maturation) within the individual, repeated testing, statistical regression, and differential loss of subjects
External validity	To what extent can the results be generalized or extended to persons, settings, times, measures, and characteristics other than those in this particular experimental arrangement?	Possible limitations on the generality of the findings because of characteristics of the sample; therapists; or conditions, context, or setting of the study
Construct validity	Given that the intervention was responsible for change, what specific aspects of the intervention or arrangement were the causal agents; that is, what is the conceptual basis (construct) underlying the effect?	Alternative interpretations that could explain the effects of the intervention, that is, the conceptual basis of the findings, such as attention and contact with the subject, expectancies of subjects or experimenters, cues of the experiment
Statistical conclusion validity	To what extent is a relation shown, demonstrated, or evident, and how well can the investigation detect effects if they exist?	Any factor related to the quantitative evaluation that could affect interpretation of the findings, such as low statistical power, variability in the procedures, unreliability of the measurement, inappropriate statistical tests

Source: Kazdin (1994).

A basic premise of Cook and Campbell's definitions of IV and EV is that the term "validity" can only be used in an approximate sense. They would say, for example, that judgments of the validity of the conclusions that can be drawn from a study must always be understood as approximate because, from an epistemological perspective, we can never definitively know what is true, only that which has not been shown to be false.

3.10.2.2 Internal Validity

Simply stated, IV refers to the extent to which causal conclusions can be correctly drawn from a study about the relationship between an independent variable (e.g., a type of therapy) and a dependent variable (e.g., symptom change). The full definition reads: "Internal validity refers to the approximate validity with which we infer that a relationship between two variables is causal or that the absence of a relationship implies the absence of cause" (Cook & Campbell, 1979, p. 37).

3.10.2.3 External Validity

EV refers to the extent to which causal conclusions from a study about a relationship between interventions and outcomes can be assumed to generalize beyond the study's specific features (e.g., the patient sample, the therapists, the measures of outcome, the study setting). The full definition of EV is: " … the approximate validity with which we can infer that the presumed causal relationship can be generalized to and across alternative measures of the cause and effect and across different types of persons, settings, and times" (Cook & Campbell, 1979, p. 37).

3.10.2.4 Construct Validity

In their 1979 update of Campbell and Stanley (1963, 1966), Cook and Campbell highlighted two new concepts that are closely linked to IV and EV: CV and SCV. Both have been incorporated into contemporary thinking about experimental design and threats to IV and EV (e.g., Kazdin, 1994).

Cook and Campbell (1979) focused their discussion of CV on the "putative causes and effects" (i.e., interventions and outcomes) of intervention studies. CV reflects the addition of a concept developed earlier by Cronbach and Meehl (1955) to Cook and Campbell's (1979) model of experimental validity. Simply stated, CV is the goodness of fit between the methods used to operationalize constructs (interventions and outcome variables) and the referent constructs. In other words, CV is the extent to which the methods used to measure and operationalize interventions and outcomes are likely to reflect the constructs that the investigators say they studied (e.g., cognitive therapy and depression). A more precise definition of CV is: " … the possibility that the operations which are meant to represent a particular cause or effect construct can be construed in terms of more than one construct, each of which is stated at the same level of reduction" (p. 59). For example, the more possible it is to construe measures in terms of constructs other than those named by the investigators, the lower the CV.

CV also can be described as "what experimental psychologists are concerned with when they worry about 'confounding'" (Cook & Campbell, 1979, p. 59). An example of a threat to CV is the possibility that the effects of a medication for depression are due largely to the treating psychiatrist's concern for a patient and nonjudgmental reactions to his or her symptoms, rather than to neurochemical effects of the drug. Such alternative interpretations of the therapeutic cause of outcomes in medication intervention studies lead to: (i) the inclusion of pill placebo control conditions, (ii) randomized assignment to either active drug or pill placebo, and (iii) the use of double-blind procedures, that is, neither treater nor patient knows if the patient is receiving active drug or placebo.

Cook and Campbell (1979) link CV to EV. They say that generalizability is the essence of both. However, an integral aspect of CV is the adequacy with which the central variables of an intervention study (the interventions and outcomes) are operationalized. Thus, CV is also necessarily linked to IV: the CV of the methods used to measure and operationalize interventions and outcomes affects the validity of any causal conclusions drawn about a relationship between the designated interventions and outcomes.

3.10.2.5 Statistical Conclusion Validity

SCV is described by Cook and Campbell (1979) as a component of IV. SCV refers to the effects of the statistical methods used to analyze study data on the validity of the conclusions about a relationship (i.e., covariation) between interventions and outcomes. SCV concerns "particular reasons why we can draw false conclusions about covariates" (Cook & Campbell, 1979, p. 37). It "is concerned … with sources of random error and with the appropriate use of statistics and statistical tests" (p. 80). For example, a determinant of SCV is whether the assumptions of the statistical test used to analyze a set of outcome data were met by the data.

3.10.3 COMMON THREATS TO IV, EV, CV, AND SCV

A study's IV, EV, CV, and SCV are determined by its design and methods, by the psychometric adequacy of its measures and operationalizations of central constructs, and by the appropriateness of the statistical tests used to analyze the data. All must be assessed to evaluate a study's IV, EV, CV, and SCV. "Design" refers to elements of a study's construction (the situation into which subjects are placed) that determine the probability that causal hypotheses about a relationship between the independent and dependent variables can validly be tested. For example, a design feature is the inclusion of a no-treatment control group of some type (e.g., pill placebo) in addition to the treatment group. A no-therapy group provides outcome data to compare with the outcomes of the treated group. The comparison allows examination of the possibility that changes associated with the treatment also occur without it and, thus, cannot be causally attributed to it.

"Methods" refers to a wide variety of procedures that are used to implement study designs, such as random assignment of subjects to each intervention group included in a study. A study's methods and design together determine the degree to which any relationship found between interventions and outcomes can validly be attributed to the interventions rather than to something else. In other words, study methods and design determine whether alternative or rival interpretations of findings can be dismissed as improbable. Designs and methods that affect a study's IV, EV, CV, and SCV are discussed in Section 3.10.4.

The use of IV, EV, CV, and SCV to guide study design and critical appraisal of study findings is assisted by knowledge of common threats to each type of validity. Cook and Campbell (1979) discussed several threats to each type. They cautioned, however, that no list is perfect and that theirs was derived from their own research experience and from reading about potential sources of fallacious inferences.

The threats to each type of validity identified by Cook and Campbell are listed in Tables 2–5. The tables also present examples of designs and methods that can offset the various threats ("antidotes"). The interested reader is encouraged to review Cook and Campbell's discussion of threats to IV, EV, CV, and SCV; design and methodological antidotes to the threats; and limitations of common antidotes.

In the following sections, the four types of threats to validity are discussed in turn. In each section, examples of designs and methods are described that are used in contemporary psychological and pharmacological mental health treatment research to enhance that type of validity. Only a sampling of designs and methods relevant to each type of validity is described due to space limitations.

3.10.4 EXPERIMENTAL DESIGNS AND METHODS THAT ENHANCE IV, EV, CV, AND SCV

Each design and method discussed in the sections that follow is limited in the extent to which it can ensure that a particular type of experimental validity is achieved. Some limitations result mainly from the fact that patient-subjects are always free to deviate from research treatment protocols they enter, by dropping out of treatment, for example. Other limitations arise because research methods that can enhance IV can simultaneously reduce EV. For example, using psychotherapists who are experts in conducting a form of therapy can both increase IV and reduce EV.

One point merits emphasis. The experimental validity potential of alternative designs and methods is always contingent on the match between study hypotheses and a study's design and methods. For example, the IV potential of a particular design differs if the main aim of a study is to obtain data that can be interpreted as evidence for a therapy's hypothesized effects vs. to obtain data that can be interpreted as evidence for the comparative efficacy of alternative therapies for the same problem.

3.10.4.1 IV Methods and Designs

Table 2 lists and defines common IV threats. The text that follows elaborates on some of the information in Table 2.

3.10.4.1.1 Random assignment

Random assignment of subjects to all intervention groups in a study design is a *sine qua non* of IV. Broadly defined, random assignment means that a procedure is used to ensure that each new subject has an equal chance to be assigned to every intervention condition in a study. A simple random assignment procedure is the coin flip: heads the subject is assigned to one intervention in a two-intervention study; tails he or she receives the other one. Various procedures are used for random assignment including sophisticated techniques like urn randomization (Wei, 1978). Urn randomization simultaneously helps ensure that subjects are randomly assigned to interventions, and that the subjects in each one are matched on preidentified characteristics (e.g., co-present problems) that might moderate the effects of an intervention (Baron & Kenny, 1986).

Random assignment contributes to IV by helping to ensure that any differences found between interventions can be attributed to the interventions rather than to the subjects who received them. The rationale for randomization is that known and unknown characteristics of subjects that can affect outcomes will be equally distributed across all intervention conditions. Hence, subject features will not systematically affect (bias) the outcomes of any intervention.

Random assignment has limitations as a way to enhance IV. For example, it is not a completely reliable method to ensure that all outcome-relevant, preintervention features of subjects are equally distributed across intervention conditions. Even when randomization is used, by chance some potentially outcome-relevant subject characteristics can be more prevalent in one intervention than another (Collins & Elkin, 1985). This fact can be discovered *post hoc* when subjects in each intervention are found to differ on a characteristic (e.g., marital status) that is also found to relate to outcome. This happened, for example, in the US National Institute of Mental Health's Treatment of Depression Collaborative Research Program study (Elkin et al., 1989).

Attrition (e.g., of subjects, of subjects' outcome data) also limits the IV protection provided by random assignment (Flick, 1988; Howard, Cox, & Saunders, 1990; Howard, Krause, & Orlinsky, 1986). For example, subjects can always drop out of treatment or fail to provide data at all required assessment points. Both are examples of postinclusion attrition in Howard, Krause et al. (1986) terminology. The problems associated with, and types of, attrition have been carefully explicated (Flick, 1988; Howard, Krause et al. 1986). For example, the core IV threat associated with dropout is that the subjects who drop out of each study intervention might differ somehow (e.g., severity of symptoms). This would create differences in the subjects who complete each intervention and simultaneously

Table 2 Internal validity.

Threat	*Description*	*Example antidote*
Historical factors	Events that occur between pre- and postintervention measurement could be responsible for the intervention effects found (e.g., a public information campaign to reduce drug use in teenagers coincides with an adolescent drug treatment intervention study)	If historical the event does not overlap completely with the study period, the outcome data can be analyzed separately for subject cohorts that received the intervention before the event vs. during it, and results compared to estimate the intervention's effects independent of the event
Maturation	Changes in subjects that naturally occur with the passage of time could be responsible for pre- to postintervention changes in outcomes	Include a no or minimal treatment control condition in the study, and randomize subjects to treatment conditions
Testing	Pre- to postintervention changes on outcome measures could be due to repeated administration of the measures, rather than to change in the outcome variables assessed	Evaluate the impact of repeated testing by administering the outcome measures to a randomly selected subset of subjects only at postintervention. Compare the final scores with those of subjects to whom the measures were repeatedly administered. Use the Solomon Four-Group design (Campbell & Stanley, 1963; Rosenthal & Rosnow, 1991) to examine both the effects of repeated testing and any interaction of testing and interventions
Instrumentation	Pre- to postintervention differences in the way an outcome measure is administered could be responsible for intervention effects (e.g., different diagnosticians administer a structured diagnostic interview at pre- and at post-test to the same subject)	Keep instruments and administration procedures constant throughout a study (e.g., recalibrate laboratory instruments and human assessors during study)
Statistical regression	Change in pre- to postintervention scores include "normal" drift toward more moderate scores whenever an initial score is either higher or lower than the average (mean) tendency of the group	Use the statistical technique of covarying preintervention scores from termination scores in outcome analyses (e.g., analysis of covariance, multiple regression)
Selection	Differences between subjects assigned to a study's intervention conditions could account for outcome differences in the interventions	Randomly assign subjects to intervention conditions
Attrition or mortality	Differences between subjects who complete each study intervention (e.g., due to dropout from the interventions) could be responsible for differences in intervention outcomes	Collect outcome data at every planned assessment point from *all* subjects (including dropouts and those withdrawn due to deterioration) and conduct outcome analyses on the 'intention-to-treat' sample (see text)
Ambiguity about the direction of causal influence	The study design does not make it possible to determine if A causes B or B causes A, although the hypotheses assume undirectional causality (e.g., in a correlational study it cannot be determined whether improvement in the therapeutic alliance enhanced outcome or if a subject's improvement enhanced the therapeutic alliance)	Do not use cross-sectional designs and standard correlational statistics if causal conclusions are desired. When theory and empirical findings exist to support causal hypotheses, one alternative is to develop and test causal models on data that lack experimental controls needed to infer causality (e.g., Kenny, 1979)

Table 2 (continued)

Threat	*Description*	*Example antidote*
Diffusion or imitation of treatments	The putative active elements of a study intervention are somehow disseminated to subjects in other intervention and/or control conditions (e.g., subjects who receive a treatment for drug addiction give copies of their treatment workbooks to subjects in the control condition)	When informed consent is administered, emphasize the requirement to refrain from discussing one's treatment with other subjects. Guarantee all subjects the opportunity to receive a study treatment (e.g., at the end of the study)
Compensatory equalization of treatments	Personnel who have control over desirable interventions compromise the study design by somehow making them available to all subjects. For example, in a study in which therapists serve as their own controls (the same therapists administer the interventions and control treatment conditions), therapists have difficulty refraining from using elements of the study's "active" interventions in the therapy sessions of subjects who are in the control condition	Ensure that subjects who do not get the desirable intervention during the study will have access to them after the study. Let subjects know at the beginning of the study that this will happen. Antidotes for the therapist example are to audiotape all therapy sessions and monitor the tapes for therapists' adherence to the intervention conditions. Immediately give therapists feedback when they deviate from adherence requirements. Also, offer all subjects who are randomized to control conditions the opportunity to receive the (putative) active treatments at the end of the study; inform therapists at the study outset that control subjects will have the opportunity to receive an active treatment
Compensatory rivalry by respondents receiving less desirable treatments	Subjects are aware of all intervention conditions in the study, and those in a "standard" condition are motivated to outperform those in "special" intervention conditions. Thus, any differences or lack of differences found between intervention and/or control conditions cannot be attributed to the interventions	This threat applies only to some types of intervention studies. For example, it can occur when a study setting is an intact unit (such as a department) and subjects in the standard condition expect some negative personal effect (e.g., lose their jobs) of study findings. Investigators need to be aware of the potential relevance of this threat to a study and either redesign the project or take actions to reduce its potential influence (e.g., see above antidote for compensatory equalization)
Resentful demoralization of respondents receiving less desirable treatments	This threat is the opposite of the threat of compensatory rivalry. Subjects in a control or other intervention condition underperform relative to their capacity and thereby contribute to artificial differences between the intervention outcomes	Investigators need to be aware of the relevance of this threat to a particular study and either redesign the project or take actions to reduce its potential influence (promise subjects in the less desirable intervention condition the opportunity to receive it at the end of the study)

Statements in the first two columns and some in the third are abstracted from Cook and Campbell (1979).

in those who provide outcome data. This type of threat of attrition to IV has been called the "differential sieve" (Hollon, Shelton, & Loosen, 1991), an apt metaphor. If differential attrition by intervention occurs, any outcome differences could be due to the subjects from whom assessments were obtained rather than to the interventions examined.

One methodological antidote to the IV problems posed by attrition due to dropout is to conduct outcome analyses on the "intention-to-treat" sample (Gillings & Koch, 1991). The intention-to-treat sample can be defined in different ways. For example, one definition is all subjects who were randomized to study interventions. Another definition is all subjects who attended at least one intervention session. The latter type of definition is often used when investigators want to generalize outcome findings only to patients who at least are willing to try an intervention.

Intention-to-treat analyses ideally require outcome assessments of all dropouts (and of all others who discontinued treatment prematurely, such as by being withdrawn by the investigators due to treatment noncompliance or deterioration) at the time(s) when they would have been assessed if they had remained in treatment. The intent-to-treat analytic strategy also contributes to a study's EV by maximizing the probability that the findings can be assumed to generalize to all individuals who would meet the study entry criteria.

Unfortunately, intention-to-treat analyses have limitations with respect to protecting a study's IV. The reader is referred to Flick (1988) and to Howard, Krause et al. (1986) for comprehensive discussions of other methods to evaluate and reduce the effects of attrition on a study's IV and EV.

3.10.4.2 Untreated or Placebo-treated Control Group

The inclusion of a no-treatment group (e.g., wait list) or putative sham treatment (e.g., pill placebo) in a study design is required to validly answer causal questions like "Does an intervention have certain effects?" A no-treatment or placebo condition to which subjects are randomly assigned and which continues for the same duration as a putative active treatment allows several rival explanations for a relationship between a treatment and outcomes to be dismissed. For example, if the outcomes associated with an active treatment are statistically better than the outcomes associated with a control treatment, then the active treatment outcomes cannot be attributed solely to changes that occur naturally with the passage of time, maturation, or "spontaneous remission."

The inclusion of control treatment conditions of some type is logically very compelling as a way to increase an intervention study's IV. Unfortunately, the compelling logic is not mirrored in practice. Reams have been written on problems associated with designing placebo therapies that meet IV goals (e.g., O'Leary & Borkovec, 1978). For example, credibility is one issue (Parloff, 1986). How can a placebo psychotherapy be developed that has no theoretically active therapeutic ingredients but that seems equally credible to subjects as a putative active treatment?

Pill placebo conditions used in psychopharmacology research are often thought to be free of the IV limitations associated with psychotherapy placebos. However, pill placebo conditions are also limited in terms of IV. For example, active medications almost always have side effects. Thus, the placebo pill used should mimic the side effects of the active drug. It also is important that both the subject and the prescribing therapist be blind (uninformed) about who is getting placebo and who is getting active medication. Experienced psychopharmacologists often, probably typically, can tell which subjects are receiving active medication (Greenberg, Bornstein, Greenberg, & Fisher, 1992; Margraf et al., 1991; Ney, Collins, & Spensor, 1986; Rabkin et al., 1986). The failure of the blinding procedure is problematic because therapists' impressions could be associated with different behavior toward placebo and active medication subjects. For example, a therapist might be less encouraging about the possibility of improvement if he or she suspects that a subject is getting placebo rather than medication. Differential therapist behavior toward placebo and active medication subjects could affect outcomes and thereby reduce the IV of the study design.

Another common threat to the IV value of no-treatment and placebo treatment conditions is contamination or diffusion. Putative therapeutic elements of an intervention can somehow infiltrate the control condition. A well-known example of this is the "MRFIT" study conducted in the USA. It was designed to evaluate an educational intervention to reduce the incidence of heart disease in men. The intervention provided information about diet, smoking, and exercise as a way to lower cholesterol and other risks of heart disease (Gotto, 1997; Multiple Risk Factor Trial Interventions Group, 1977). The study design was a randomized, controlled comparison of men who received the intervention with men who received "usual care." During the years that the study was done, information used in the intervention was widely disseminated in the US media, thus threatening the IV value of the usual care control sample.

Another way contamination of a control treatment can occur is via contact between the control subjects and those receiving the active treatments. For example, subjects in active treatments might give control subjects intervention materials (e.g., copies of intervention self-help workbooks). To help prevent this threat to IV, subjects can be required, as part of the study informed consent, to refrain from sharing information about their respective treatments while a study is in progress.

3.10.4.3 Specification of Interventions

A relatively new set of IV methods focuses on detailed specification of the interventions examined in a study. These methods have been adopted widely in psychotherapy research since the 1980s. Their primary aims are to facilitate replication of studies and to ensure that interventions are properly implemented. The methods include the preparation of treatment manuals (e.g., Beck, 1995; Klerman, Weissman, Rounsaville, & Chevron, 1984), for example. Such manuals describe the treatment rationale, the therapeutic techniques to be used, and the circumstances that should prompt therapists to choose between alternative techniques (Lambert & Ogles, 1988). The methods also include the development of therapist adherence measures to be used by observer-judges of therapy session material (e.g., audiotapes) to assess the extent to which treatments were delivered by study therapists as specified in the manual (Waltz, Addis, Koerner, & Jacobson, 1993).

Treatment specification methods are described more fully in Section 3.10.4.7 on CV. They are cross-referenced here to emphasize the fundamental dependence of a study's IV on the CV of its intervention variables. The dependence is essentially the same as that between the psychometric adequacy of the measures and methods used to operationalize independent and dependent variables, and the possibility of conducting a valid test of hypotheses about the relationship between independent and dependent variables (Kraemer & Telch, 1992). The validity of conclusions about hypotheses is necessarily contingent on the adequacy of the operationalization of central study variables or constructs. The preceding point, albeit basic, merits emphasis because it is often ignored or not understood well in mental health intervention research (Kraemer & Telch, 1992).

3.10.4.4 Process Research Methods

"Process" research refers to a highly developed methodology that has been used in adult psychotherapy research since at the 1950s (Greenberg & Pinsof, 1986; Kiesler, 1973; Rice & Greenberg, 1984; Russell, 1987). Described generally, process research is the application of measurement methods to therapy session material, such as videotaped recordings or transcripts of therapy sessions. A typical strategy for process research consists of four basic steps. First, a measure is developed of a theoretically important therapy construct (e.g., therapeutic alliance). The measure is designed to be rated by trained judges, based on observation of some type of therapy session material (e.g., videotapes of sessions). Judges are selected and trained to apply the measure. Psychometric studies are done to evaluate and ensure that judges' ratings on the measure meet standards for inter-rater reliability. A plan for sampling material from therapy sessions for judges to rate is developed. The sampling plan is designed to provide a valid idea of the construct. Judges then rate the selected material. In addition to the foregoing basic steps, it is also important to conduct psychometric evaluations of measure (e.g., the internal consistency reliability of ratings).

Process methods are used to examine a host of research questions (for comprehensive reviews see Orlinsky & Howard, 1986; Orlinsky, Grawe, & Parks, 1994). One of the most valuable uses of process research methods is to test the theories of therapeutic change that are associated with different types of psychotherapy. A standard treatment outcome study is designed to ask questions like "Does a treatment work?" and "Does a therapy work better than an alternative one for the same problem?" Process methods allow the next logical questions to be asked, for example, "Does a therapy work for the reasons it is theoretically posited to?" and "What are the therapeutically active elements of a therapy?" Viewed in terms of Cook and Campbell's (1979) types of experimental validity, process research methods contribute mainly to IV and CV.

Process methods can contribute to a study's IV when they are used to test hypothesized relationships about theoretically causal elements of a therapy (such as specific therapeutic techniques) and targeted outcomes. The precision of the causal conclusions that can be drawn from intervention studies is limited when patients are randomly assigned to treatments, receive treatment, and then outcomes are measured. Even when intervention outcome studies yield positive findings, many fundamental and important questions remain unanswered. Are a therapy's effects mediated by the theoretically hypothesized activities of therapists? Alternatively, are the effects primarily due to nonspecific features of the therapy (e.g., the therapist's empathy and understanding) rather than to its specific techniques (e.g., cognitive restructuring)? (Ilardi & Craighead, 1994; Kazdin, 1979; Strupp & Hadley, 1979). Are all of the recommended therapeutic techniques necessary; are any necessary and sufficient?

Process methods can be used to examine questions of the foregoing type. When used in such ways, they contribute to a study's IV because they help elucidate causality, that is, the extent to which specific elements of a therapeutic intervention can validly be assumed to play a causal role in the outcomes obtained

(Gomes-Schwartz, 1978). Furthermore, when process research methods yield answers to mechanisms of action questions like those stated above, the findings can be used to refine and improve existing treatments, for example, to increase their efficiency and efficacy, and to modify the theories of therapeutic change on which treatments are founded.

Process methods can also contribute to CV. For example, process methods are used both to develop instruments to assess therapists' adherence to manualized treatments (e.g., Evans, Piasecki, Kriss, & Hollon, 1984), and to develop a rating strategy (e.g., plan for sampling from the therapy session material to be rated by judges) to assess therapist adherence for intervention studies (e.g., Hill, O'Grady, & Elkin, 1992). More detail is provided on process research methods that contribute to CV in Section 3.10.4.3.

3.10.4.5 EV Methods

Table 3 presents three types of threats to EV that were highlighted by Cook and Campbell (1979). Each threat is described as an interaction between a study feature and the study treatment(s). This is because Cook and Campell emphasized the difference between generalizing *across* subject populations, settings, etc., vs. generalizing *to* target subject populations, settings. Cook and Campbell chose to focus on the former because the latter requires sophisticated random sampling methods which are rarely used in intervention research.

As stated earlier, EV concerns the extent to which outcome findings validly can be assumed to generalize beyond a study's specific therapists, subjects, setting(s), measures, and point in time when a study was conducted. For about the past eight years in the USA, criticisms have been raised increasingly often about intervention studies with apparent low EV (e.g., Lebowitz & Rudorfer, 1998). The criticisms are part of the efficacy vs. effectiveness debate. For example, it is said that the outcomes of therapies done by study therapists who are trained in a therapy and then receive ongoing supervision during a study (to ensure that they continue to adhere to the therapy manual) cannot be assumed to generalize to community therapists who might provide the treatment. The generalizability point is a valid one. At minimum, it underscores the need for therapist training methods and materials to be made widely available for interventions found to be efficacious in high IV studies.

Contemporary controversies aside, methods that can contribute to EV are described next. Some of their limitations are also noted.

3.10.4.5.1 Naturalistic treatment settings

The ultimate aim of psychotherapy intervention studies is to identify therapies that can be provided effectively in settings where individuals who have the problems that are targeted by the therapy are treated. However, studies with the highest IV, for example, those that include random assignment and a placebo treatment, are often done in university-affiliated clinic settings. Such settings are where researchers tend to be located. The settings also tend to be most amenable to the implementation of research methods that are needed for high IV studies.

University-affiliated clinical settings differ in many ways from other settings in which mental health interventions are provided, such as urban and rural community mental health clinics and private practice offices. The differences between a study's setting(s) and the settings to which it is important to generalize its findings reduce EV only if the differences affect the outcomes of the interventions being tested. Thus, to accurately evaluate a study's EV with respect to nonstudy settings, one must know which setting features affect the outcomes of the interventions. Unfortunately, research generally is not done on the foregoing topic. In the absence of knowledge, the prevailing convention seems to be to adopt a conservative position: namely, the more similar to "typical" mental health treatment settings that an intervention study setting is, the greater the study's probable EV.

The foregoing convention results in recommendations like: a study protocol that has high IV should be implemented in a variety of public and private mental health treatment settings, both urban and rural, and in different sections of a country (i.e., in large countries where areas exist that have different subcultures). Unfortunately, the preceding strategy to enhance the EV of settings is rife with limitations (cf. Clarke, 1995). Cook and Campbell (1979) extensively discussed the problems, which they referred to as "major obstacles to conducting randomized experiments in field settings." They also discussed social forces and field settings that are conducive to randomized intervention studies.

A common obstacle is that all community clinics have standard operating procedures. The need to introduce the key IV-enhancing experimental method, random assignment, typically is an enormous challenge in such settings. At minimum, it requires that all regular clinic staff, or at least a representative sample of them, be willing to learn and to correctly implement a new intervention. Assuming that the staff are interested in being trained in a new intervention,

Table 3 External validity (generalizability).

Threat	*Description*	*Example antidote*
Interaction of selection and treatment	The study's subject inclusion and exclusion criteria and/or other requirements of study participation could result in a sample that responds differently to the intervention(s) than would other individuals of the type for whom the intervention(s) was designed.	Make entry into the study as convenient as possible to maximize the representativeness of the sample of the desired population. Attempt to replicate the study using modified inclusion criteria (e.g., drop the prerandomization study induction procedure that was used in the original study)
Interaction of setting and treatment	Features unique to the study setting(s) could contribute to the intervention effects (e.g., the setting was a well-known treatment and research clinic, famous for one of the interventions)	Attempt to replicate the study by simultaneously or consecutively carrying out the same design and procedure in two or more settings
Interaction of history and treatment	Features unique to the time when the study was done could contribute to the intervention effects (e.g., a study of therapies for depression was conducted during the same year that the US National Institute of Mental Health ran a major public information campaign on the efficacy of psychological therapies for depression)	Attempt to replicate the study

Statements in the first two columns and some in the third are abstracted from Cook and Campbell (1979). The threats are listed as interactions between variables and study treatments because the threats apply when the intention is to generalize *across* populations, settings, etc., rather than *to* target populations, settings, etc. Cook and Campbell provide an extended discussion of the difference.

training time must be made available to them. The need for training can pose a major hurdle because staff work days typically are fully booked with existing job responsibilities.

An alternative is to hire new clinic staff specifically to conduct treatments for a study. This strategy typically is associated with pragmatic limitations such as office space. Also, hiring new staff can compromise the setting EV goal, the main reason for wanting to conduct an intervention study in a field setting.

3.10.4.6 Inclusive Subject Selection

Mental health interventions are developed to be helpful to individuals who have particular types of problems. Hence, subject EV is a critical type of EV for an intervention study. Several threats to subject EV that are associated with procedures which enhance IV have been described (e.g., Howard, Cox, & Saunders, 1990; Howard, Krause et al., 1986). For example, IV requires that subjects accept random assignment to any intervention condition in a study. Some study applicants will refuse to participate due to this requirement. Such refusal is a threat to EV because the study sample will not be representative of all individuals for whom the study intervention is believed to be appropriate. Also, studies with high IV typically require subjects to participate in research assessments, often extensive ones. Some require subjects to agree to audio- or videorecording of therapy sessions. A portion of potential subjects are likely to refuse participation due to assessment requirements, thereby reducing the subject EV of study findings. All of the preceding examples are types of preinclusion attrition.

The fundamental threat to IV posed by subject dropout from treatment studies (post-inclusion attrition) was described previously. Dropout is also a serious, predictable, and often intractable EV threat. Researchers' careful selection, implementation, and description of subject inclusion and exclusion criteria all potentially enhance a study's EV by providing specific information on the types of individuals to whom the findings are most likely to generalize. The loss of outcome data that typically is associated with subject dropout compromises the confidence with which it can be concluded that a study's findings generalize to individuals like those selected for the study. The threat to EV of subject dropout is another reason why it is critically important to try to obtain data at all required assessment points from all subjects who enter a study, dropouts and remainers alike.

One of the most frequent subject EV criticisms of contemporary US studies with high IV is their psychodiagnostic inclusion and exclusion criteria (e.g., American Psychiatric Association, 1994). The criticism is that the use of specific diagnostic critieria for sample selection yields subjects who are unrepresentative of individuals who would receive the interventions in community settings. Study samples are said to be highly selected, consisting of "pure" types that are unrepresentatively homogeneous compared to treatment-seeking individuals who contact field clinical settings (e.g., Lebowitz & Rudorfer, 1998; Seligman, 1995).

The preceding subject of EV concern is a relatively new one. It relates directly to a mental health intervention research strategy that developed in the USA after 1980, when the third edition of the *Diagnostic and statistical manual of mental disorders* (*DSM*; American Psychiatric Association, 1980) was published. Shortly thereafter, sociopolitical forces converged to contribute to the requirement that applications for federal grant funding for mental health intervention efficacy studies be focused on specific diagnoses (e.g., major depressive disorder; social phobia) as defined in the *DSM*. Previously, the sample selection criteria for such studies were very broad, for example, treatment-seeking adults who complained of a variety of "problems in living" but who had no history of a psychotic disorder or current drug addictions.

The validity of the foregoing subject of EV criticism merits examination. It is true that the trend in intervention research in the USA since 1980 has been to develop and test interventions for relatively specific symptoms and syndromes (e.g., depression). However, study reports generally do not include comprehensive descriptions of co-present diagnoses (i.e., comorbidity patterns) of subjects. Thus, the extent to which most study samples are indeed more homogeneous than community setting patients for whom an intervention would be recommended typically cannot be determined. Also, some evidence from research clinics is beginning to appear that does not support the homogeneity criticism (e.g., Kendall & Brady, 1995).

3.10.4.6.1 Staff therapists

Another commonly mentioned threat to EV is the use of specially selected therapists. For example, sometimes investigators limit study therapists to a subset who meet a criterion of skillfulness. The rationale is that delivery of study interventions by therapists who are optimally skilled will provide the most accurate test of an intervention's efficacy. However, the strategy also poses a threat to EV. Can the outcomes of a study in which expert therapists delivered the interventions be assumed to generalize to less skilled therapists? The most conservative answer to this EV question is probably not. However, many contemporary intervention studies with high IV also specify (i) methods to identify therapists like those selected for a study, and (ii) therapist training programs that include ways to measure skill attained before therapists start to treat study patients. Thus, high IV studies that meet current methodological standards describe ways to identify and train nonstudy therapists who are like study therapists and, thus, who are likely to provide treatments that have outcomes similar to those obtained (cf. Kazdin, Kratochwill, & VandenBos, 1986).

3.10.4.6.2 CV Methods

Table 4 summarizes threats to CV and lists some antidotes. The text that follows elaborates on some of the information in Table 4.

In Cook and Campbell's 1979 discussion of CV, they opined that "most applied experimental research is much more oriented toward high construct validity of effects than of causes" (p. 63). Their observation was accurate for psychotherapy intervention research at the time but, notably, does not hold for therapy research published since about 1990 (e.g., Elkin et al., 1989). A methodological revolution in psychotherapy research enabled the CV of putative causes, that is, therapeutic interventions, to be enhanced. The relevant new methods are described in Sections 3.10.4.7.1–3.10.4.7.3.

3.10.4.6.3 Specification of interventions: treatment manuals

Cook and Campbell (1979) highlighted the dependence of CV on careful pre-operationalization explication of the essential features of study constructs. Prestudy preparation of treatment manuals, discussed in Section 3.10.4.1.3, is a research method that achieves pre-operationalization explication of the intervention construct, if done well. Criticisms of the treatment manual revolution in therapy research have been frequent and heated, despite the critical contribution of manuals to both the IV and potential EV of psychotherapy intervention studies

Table 4 Construct validity of putative causes and effects.

Threat	*Description*	*Example antidote*
Inadequate preoperational explication of construct	The researchers' elucidation of one or more of the main study constructs (i.e., the interventions and outcome) was not adequate to guide valid operationalization (measurement) of them	Devote necessary resources to identifying or developing valid operationalizations of interventions and outcomes because high construct validity of intervention and outcome variables is essential to conducting interpretable intervention research
Mono-operation bias	Reasonable variation in the implementation of an intervention does not occur (e.g., only male therapists are used) which reduces the validity of the operationalization of the intervention	Vary putatively irrelevant features of study interventions (e.g., use male and female therapists who represent a wide age range to deliver interventions)
Monomethod bias	Only one measurement method is used to assess central variables (e.g., all outcome measures use the paper and pencil self-report method) which confounds variance in scores due to method with variance that reflects the variable of interest	Include measures of central variables that are based on more than one assessment method (e.g., self-report and behavioral observation of symptoms)
Hypothesis-guessing within experimental conditions	Subjects try to intuit the study hypotheses and skew their responses based on what they think the hypotheses are	Try to make hypotheses hard to guess or intentionally tell subjects false hypotheses (and debrief them after the study is over). Tell subjects who are in a treatment outcome study that honest, candid responses are more useful to the research than trying to "help" the researcher by showing improvement on measures.
Evaluation apprehension	Subjects might present themselves more positively (or more negatively) than their honest self-evaluation when they are being assessed by experts in personality, psychopathology, or basic human skills	Use paper and pencil self-report measures of the same constructs that "expert" interviewers assess; include measures of social desirability response style, and use them as covariates if they are correlated with scores on outcome measures. Administer measures of socially undesirable variables at a prestudy baseline point and again immediately before study begins. Assume that the second administration is likely to be the more valid (candid) index
Experimenter expectancies	Investigators' biases influence the study findings	Investigators should not administer study interventions. Conduct the same study protocol in two or more settings, each of which is overseen by an investigator with a different preference (bias) for the interventions examined
Confounding constructs and levels of constructs	Some interventions might be differentially efficacious when provided at different levels or strengths (e.g., doses of psychotropic medications; a psychotherapy conducted with two sessions per week for the first 12 weeks vs. once weekly for the first 12 weeks)	Conduct a study to examine whether an intervention's effects differ by the strength of the "dose" administered

Table 4 (continued)

Threat	*Description*	*Example antidote*
Interaction of different treatments	Subjects concurrently receive nonstudy interventions and the study intervention (e.g., some subjects in a psychotherapy study start taking psychotropic medications; in a study of medication treatment for drug addiction, some subjects also receive medical and housing help at the study clinic)	Use procedures to reduce the probability that subjects will receive treatments other than the study treatments. For example, as a criterion for study participation, require subjects to refrain from taking psychotropic medications or having any other psychotherapeutic treatment while in the study. Check throughout a study for use of proscribed treatments and either withdraw subjects from study or exclude the data of subjects who use proscribed treatments from outcome analyses
Interaction of testing and treatment	The study assessment procedures affected the response of subjects to study interventions (e.g., a preintervention measure sensitized subjects in a way that enhanced their response to the study intervention)	Examine the presence of this threat experimentally by administering the measures to two subject samples. Administer tests to one sample at pre- and postintervention; administer to other only at postintervention. A complete Solomon four-group design (Campbell & Stanley, 1963) can also be used
Restricted generalizability across constructs	Interventions can affect many important outcome variables. However, effects on outcomes (constructs) of interest often are not highly correlated (generalizable)	Include measures that are closely related to the main outcomes sought with an intervention, in addition to the key outcomes (e.g., in a study of treatments for depression, include measures of severity of depression symptoms, work functioning [number of sick days], and marital conflict

Statements in the first two columns and some in the third are abstracted from Cook and Campbell (1979).

(Wilson, 1996). However, the CV of intervention constructs requires more than manuals. It also requires prestudy therapist training procedures to teach therapists how to conduct the interventions as specified in the manual. A final step is to evaluate and ensure the effectiveness of the training "manipulation" before therapists are permitted to conduct therapies with study subjects. Methods for this are discussed next.

3.10.4.6.4 Specification of interventions: therapist adherence measures

The previously mentioned process research methodology, observer-judge ratings of therapy session material, provides the most valid index available to date of the extent to which a therapist has acquired a requisite skill level with a study intervention. Some research findings support the preceding conclusion. For example, trainee therapists' scores on written tests about a therapy were not highly correlated with supervisors' judgments of trainees' skill in conducting a therapy. Likewise, supervisors' impressions of trainees' competence with a therapy, based on trainees' descriptions of therapy sessions, were not highly correlated with supervisors' ratings of trainees' competence based on videotapes of therapy sessions (Chevron & Rounsaville, 1983).

The use of process methods to assess the extent to which therapists conduct treatments as specified requires the development of adherence measures (e.g., Evans et al., 1984). Adherence measures typically consist of items that operationally define what the developers of an intervention believe to be its essential therapeutic elements. Judges review therapy session material and rate the extent to which a therapist enacts (verbally and/or behaviorally) each item as specified by the adherence measure. The development of a psychometrically sound therapist adherence measure for an intervention, including a system for sampling the therapy session material to which the measure should be applied, is a time-consuming and sophisticated research methodology.

The use of self-report therapist adherence measures recently has been proposed as a substitute for judge-rated measures (Carroll, Nich, & Rounsaville, in press). Self-report adherence measures have interesting uses in therapy research, perhaps particularly in therapy development research. However, the only psychometric examination to date of the validity of such methods as indices of therapists' adherence to a treatment as specified in a manual yielded negative results (Carroll et al., in press).

Therapist adherence measures are a way to assess the CV of study interventions. Adherence measures can be applied to systematically sampled therapy session material to yield an index of the extent to which study therapies were conducted as specified. The contribution of psychometrically sound therapist adherence measures to both CV and IV cannot be overemphasized: they allow us to evaluate whether or not the designated interventions (the independent variables) were delivered as intended in intervention studies.

The preceding discussion is a simplified explication of the issues involved. The advent of therapist adherence methodology was associated with recognition of the difference between two constructs, adherence and competence (e.g., Waltz et al., 1993). Basically, adherence denotes a therapist's *fidelity* to the therapeutic techniques that are described in a treatment manual; competence denotes *skill* in implementing the techniques (e.g., tailoring a technique to increase its acceptability to a particular client). Reseach to date is consistent with the conclusion that inter-rater reliability is more achievable with adherence measures than with competence measures. Recruiting experts in a particular form of therapy to judge competence does not solve the reliability problem (a "problem" which signals needed directions for psychotherapy outcome research at this time).

3.10.4.6.5 Distinctiveness of interventions

The main aim of some intervention studies is to compare the outcomes of alternate treatments for the same problem. A fundamental assumption of comparative treatment studies, albeit sometimes implicit, is that the interventions being compared are distinctive in terms of their putative therapeutically active elements. For example, a study that is designed to compare the outcomes of a form of cognitive therapy for depression with another type of psychotherapy for depression is based on the assumption that the therapies are substantively different somehow. The assumed distinction is what makes it worthwhile to compare therapies in a single study. In CV terms, a comparative intervention study design reflects the assumption that the intervention constructs are distinguishable. While the issue might seem moot, it is not. Therapies that sound distinct based on their theories of therapeutic change and prescribed techniques might not be distinguishable in practice, that is, when they are implemented (operationalized) in words and behaviors by therapists.

Therapist adherence measures for different interventions provide a systematic way to evaluate the distinctiveness of putatively different forms of psychotherapy and, hence, a way to evaluate the CV of comparative intervention studies. The general methodology is to apply the therapist adherence measure for each intervention to the intervention for which it was developed and to the other interventions in a study (e.g., cognitive therapy, psychodynamic therapy, and placebo therapy sessions each are rated on a cognitive therapy adherence scale and a psychodynamic therapy adherence scale). The scores obtained on the adherence measures for each intervention can then be compared to *a priori* criterion scores that are established to indicate the distinctiveness of the interventions. Hill et al. (1992) exemplifies the methodology.

3.10.4.6.6 Adjunctive therapies

When an intervention study is described as a test of a specific intervention, it is assumed that the intervention is the only one that the subjects received. However, sometimes study subjects are allowed to participate in adjunctive interventions (e.g., Alcoholics Anonymous) or are provided with additional interventions on an as-needed basis (e.g., aid from a case worker for housing and other needs; psychotropic medications). Participation in adjunctive interventions constitutes a threat to the CV of the study intervention, as well as to the study's IV. Outcome findings cannot be validly interpreted as due to the designated intervention(s) when adjunctive interventions are allowed but not controlled in some way.

3.10.4.6.7 Assessment procedures

Repeated testing on the same outcome measures is a CV threat that often is ignored. Cook and Campbell (1979) frame the issue as follows: can an intervention–outcome relationship be generalized to testing conditions other than those used in the study to assess outcomes?

For example, if an outcome measure was administered both pre- and postintervention, would the same outcomes have been obtained if the measure was administered only at postintervention? One way to examine the threat of repeated testing to the CV of outcome scores is to compare findings of two randomly assigned intervention groups: one that was both pre- and post-tested, and another that only was post-tested.

A related CV threat is the possibility that study outcome measures interact with interventions. For example, studies of cognitive-behavioral (CB) therapy for panic disorder have been criticized for the possibility that CB affects a primary outcome measure used in such studies, self-reported frequency of panic attacks, mainly by teaching subjects to redefine panic attack rather than by reducing the actual frequency of attacks. To the extent that the criticism is valid, differences in panic attack frequency found between a control intervention and CB have low IV because the outcome measure in the CB condition has low CV. The measure does not reflect change in frequency of panic attacks, it reflects change in subjects' definitions of panic attack. The Solomon Four-Group Design (Campbell & Stanley, 1963; Rosenthal & Rosnow, 1991) can be used to simultaneously evaluate main effects of repeated testing on outcome measures and interactions of interventions and measures.

A common way to reduce CV threats to an outcome measure like the one just described for panic is to include other measures of closely related constructs in a study. The other measures should not be vulnerable to the same CV threat. For example, a spouse could be asked to provide ratings of the frequency and intensity of a subject's panic attacks. (This solution is, of course, associated with other types of CV concerns.)

3.10.4.7 SCV Methods

Only a few SCV-relevant methods are discussed here due to space limitations and to the technical detail associated with many SCV issues. The reader is referred to Cook and Campbell (1979) for a more complete review and to Table 5 for a synopsis of their discussion of SCV.

3.10.4.7.1 Statistical power analysis

Conducting a statistical power analysis at the planning phase of an intervention study is critical to its SCV (Cohen, 1977, 1992; Kraemer & Thiemann, 1987; Rosenthal & Rosnow, 1991). A power analysis helps an investigator determine the minimum sample size needed to detect a statistically significant outcome difference of a magnitude that he or she regards as clinically meaningful (e.g., Jacobson & Truax, 1991), given his or her willingness to risk making a type II error (i.e., accept the null hypothesis of no difference when it should be rejected). The smaller the sample size, the greater the risk of type II error when standard statistical procedures like analysis of variance are used in intervention research. However, the larger the sample size, the more expensive, time-consuming, and less feasible a study typically becomes.

A prestudy power analysis is a computation that allows investigators to enhance a study's SCV by determining the minimum sample size needed to statistically detect an outcome difference of a specified magnitude, given expected variances in the outcome measures. Ideally, an investigator can draw on criteria of some type to determine the size of a difference (effect size) that will have applied significance, that is, be clinically meaningful (Jacobson & Truax, 1991). For example, a clinically meaningful difference is one that experienced therapists would regard as a compelling reason to recommend one treatment over another for a particular problem.

The rationale for a power analysis is as follows. The magnitude of the variances of outcome measures and the study sample size are major determinants of whether or not an outcome difference of a certain magnitude between interventions will be statistically significant (i.e., unlikely to be due to chance). The same absolute difference between mean outcome scores of two interventions could be statistically significant if the sample size in each group was 30, but not if it was 15. Another perspective on the situation is that the smaller a study's sample size, the higher the probability of a type II error if the conventional $p \leqslant 0.05$ is used to indicate statistical significance. Rosnow and Rosenthal (1989) present a compelling perspective on the fundamental importance of the foregoing issues.

3.10.4.7.2 Controlling for the type I error rate

Statistical tests commonly used in intervention research (e.g., the F-test in analysis of variance) are associated with probability values, for example, $p < 0.05$. A p value indicates the probability that a difference found between interventions is due to chance rather than a true difference. Thus, for example, a statistical test that meets the $p \leqslant 0.05$ significance level means that a difference of the same magnitude would

Table 5 Statistical conclusion validity.

Threat	*Description*	*Example antidote*
Low statistical power	Limited potential of a study to yield statistically significant intervention effects (i.e., low potential to reject the null hypothesis) due to sample size and to the probable variances of outcome measures	Conduct a power analysis (e.g., Cohen, 1977, 1992; Rosenthal & Rosnow, 1991) during the design phase of a study to determine the sample size needed to detect an intervention effect of a predetermined size
Violated assumptions of statistical tests	Failure to ensure that a study's outcome data meet the assumptions of the statistical tests used to analyze it	Know the crucial assumptions of all statistical tests used and conduct analyses needed to evaluate whether the study data meet the assumptions. Seek expert statistical consultation if needed.
Fishing and the error rate problem	Several unplanned (i.e., *a posteriori* rather than *a priori*) statistical tests of effects (fishing) are conducted but no adjustments are made to reduce the likelihood that statistically significant findings are due to chance. In other words, the probability of type II error is larger than indicated by the reported *p* values	Consult statistics textbooks for methods to handle the error rate problem (e.g., Bonferroni correction; Tukey or Scheffé multiple comparison tests)
Reliability of measures	Low test–retest reliability (stability) and/or low internal consistency reliability of outcome measures inflates the error variance in scores and thus reduces the probability of finding intervention effects	Rely on psychometric properties of measures to guide selection of study measures. Choose measures with strong psychometric properties over measures with poor or unknown psychometric properties that might have better "face validity" as measures of the construct of interest (Kraemer & Telch, 1992)
Reliability of treatment implementation	Variability in the implementation of an intervention with different subjects (lack of standardization across subjects) inflates error and, thus, reduces the probability of finding intervention effects	Train study therapists to a criterion level of adherence to interventions before they treat any study patients; monitor their adherence to the treatment manual throughout the study and intervene if drift occurs (e.g., Shaw, 1984)
Random irrelevancies in the experimental setting	Features of a study setting other than the interventions could affect outcome scores (e.g., two research assistants administer the outcome measures to subjects: one is warm and friendly and the other is abrupt and distant)	Code features of the study setting that are likely to affect outcome measures as variables and include them in the data analyses to reduce error (e.g., research assistant who administered outcome measures is coded as a variable and included as a factor in an analysis of variance that is used to test for treatment effects)
Random heterogeneity of subjects	Differences in subjects could affect scores on the outcome measures independent of any intervention effects	Measure subject characteristics that are likely to be correlated with scores on outcome measures; use the characteristics as covariates or as blocking variables

Statements in the first two columns and some in the third are abstracted from Cook and Campbell (1979).

be expected to be obtained on average five times or fewer if 100 of the statistical tests were done, if the null hypothesis of no difference between interventions were true. The use of *p* values in conjunction with statistical tests is the principal way investigators guard against type I error (rejecting the null hypothesis of no difference when it should be accepted) when interpreting study findings. Thus, conducting statistical tests in ways that maintain the interpretability of *p* values is crucial to a study's SCV.

The interpretation of a *p* value is compromised when multiple statistical tests are done but no precautions are taken to ensure that the degree of protection against a type I error remains constant. A variety of procedures exist to maintain a specified level of protection against type I error when several statistical tests are performed. Statistics textbooks describe procedures such as the Bonferroni correction (e.g., Rosenthal & Rosnow, 1991). The main point for present purposes is that conducting multiple statistical tests without adjusting the probability level of the tests compromises a study's SCV. Unfortunately, this is a common type of threat to SCV in intervention research (Dar, Serlin, & Omer, 1994).

3.10.4.7.3 Testing assumptions of statistical tests

One fundamental assumption of the statistical tests that are commonly used for outcome analyses is that the dependent (outcome) variable is normally distributed. If the data do not meet the normality assumption, then the validity of the statistical test is compromised, that is, the study SCV is threatened. A special class of statistical procedures, nonparametric statistics (Leach, 1979), exist for analyzing data that are not normally distributed. Alternatively, procedures exist to transform data (e.g., square root transformation) to make their distribution more symmetrical before applying statistical tests (Atkinson, 1985; Carroll & Rupert, 1988).

3.10.5 FROM IV VS. EV TO IV + EV IN MENTAL HEALTH INTERVENTION RESEARCH

One illustration of the centrality of IV and EV to intervention research is the aforementioned controversy on efficacy vs. effectiveness studies (e.g., Goldfried & Wolfe, 1998; Jacobson & Christensen, 1996; Lebowitz & Rudorfer, 1998; Mintz et al., 1996; Seligman, 1995, 1996). The controversy took center stage largely as a side effect of dramatic shifts in health care delivery in the USA since the mid-1980s. Two forces were particularly valent in drawing the attention of intervention researchers and consumers of their research to efficacy (IV) and effectiveness (EV) methods. The forces were (i) a move from indemnity insurance coverage for health care to managed care coverage to control costs, and (ii) the US Congress's attempt in 1993 to reform national health care. Both forces highlighted the need for valid information about interventions to guide decisions of government policymakers and managed care entrepreneurs. Both groups were motivated to make decisions rapidly that would impact the interventions that millions of Americans could receive in insured programs. The need for valid findings to inform the decisions was keenly felt by all interested parties, including researchers. Limitations of information from existing studies became widely and painfully evident. Lively debates later appeared about how intervention research in the USA, particularly federally funded research, should be designed (e.g., Clarke, 1995; Jacobson & Christensen, 1996; Lebowitz & Rudorfer, 1998; Newman & Tejeda, 1996; Seligman, 1995, 1996; Speer, 1994; Wells & Sturm, 1996).

A question at the core of the debate is how to design intervention studies to maximize three aims: (i) the value of findings in terms of definitive public health implications and enhancement, (ii) the speed with which valid and useful findings can be obtained, and (iii) the public health policy yield from relatively scarce federal funding for mental health intervention studies. Personal biases are evident in positions taken by many who have spoken on the issues (e.g., pragmatism vs. concern that policy decisions that affect large numbers of people will be made based on scientifically weak findings). However, a valuable product of the debate has been creative thinking about how IV and EV goals might be maximized, for example, via new study questions and methods, and the use of statistical techniques such as causal modeling (Kenny, 1979). Interestingly, Cook and Campbell (1979) were keenly aware of all three of the aforementioned aims in the late 1970s. The ideas developed in all editions of their book, particularly in the sections on quasiexperimental designs, were largely intended to address them.

The current debate illustrates the importance of being fully fluent with the concepts of IV and EV for both creators and consumers of intervention research. A few suggestions from the debate for mounting studies that have both high IV and EV are described next. Then, two illustrative IV + EV studies are reviewed in terms of IV and EV.

3.10.5.1 Strategies for Efficacy + Effectiveness (IV + EV) Intervention Studies

Most strategies for designing intervention studies that optimize both IV and EV that have emerged so far from the efficacy vs. effectiveness debate are intended to maximize the applied public health (utilitarian) information that is obtained from studies. However, to test treatments that hold promise as marked advances over currently available interventions, high IV designs and methods are likely to be the most informative research strategies, due to their suitability for theory-testing and for testing causal hypotheses (Jacobson & Christensen, 1996; Mintz et al., 1996). The IV + EV strategies described here were selected to illustrate the diversity of approaches that have been proposed. Each strategy is described briefly, in a way intended to highlight its essence.

3.10.5.1.1 The conventional "phase" strategy

Before the recent efficacy vs. effectiveness debate, federal agencies that funded mental health research in the USA endorsed a phase model to meet the goals of IV and EV inference. According to Hoagwood et al. (1995), the phase model was adapted from one used by the US National Cancer Institute. Described in a simplified way, the model is to conduct efficacy studies of interventions for which promising outcome data were obtained in prior, preliminary research; the next phase is to conduct effectiveness studies of interventions for which compelling efficacy data are obtained.

3.10.5.1.2 A dimensional adaptation of the phase model

Hoagwood et al. (1995) identified several reasons why the phase model, although elegant, is rarely fully realized. A major hurdle has been moving interventions with demonstrated efficacy to effectiveness studies. A typical stumbling block to the transfer is introducing research methods into community settings to conduct effectiveness studies. Hoagwood et al. presented an alternative strategy, the essence of which is to conceptualize efficacy and effectiveness goals "in terms of continuous dimensions, rather than discrete phases" (p. 685). The authors describe a conceptual framework, not a model *per se*. It is linked specifically to mental health interventions for children, adolescents, and families.

The framework emphasizes three bipolar dimensions of intervention research, each of which can be described as having an IV and an EV pole. The dimensions are types of validity, types of intervention modalities and parameters, and types of outcomes. For example, at the IV pole of the intervention dimension are short-term (e.g., three months), highly structured, single modality therapies that are operationalized in detailed manuals; at its EV pole are longer-term, less well-specified treatments that allow for the integration of more than one therapy modality.

3.10.5.1.3 Stakeholder's model to guide data selection

Newman and Tejada (1996) highlighted the need to collect data that are sought by all parties who have a vested interest in mental health interventions (the stakeholders). The authors endorsed the view that high IV studies have an essential role in intervention research because they provide scientifically well-founded, important information about interventions, for example, their potential effects and their safety. EV goals are accomplished in the stakeholders model mainly by *collecting certain kinds of outcome and other data* about interventions that can help inform the decisions of all stakeholders in mental health treatment (e.g., government policymakers and corporate officials of managed care companies; potential recipients of interventions; family members and others who are directly affected by those who receive mental health interventions).

Types of data emphasized by Newman and Tejada (1996) include costs of interventions and estimates of the amount of therapeutic effort required to obtain specified behavioral outcomes. Hoagwood et al. (1995) also included cost data in their framework. The need for cost data (e.g., cost-effectiveness, cost-offset, comparative cost) is a dominant theme in research strategies that have been proposed for efficacy + effectiveness studies. This emphasis is largely a response to increasing concerns about, and concomitant restrictions on, health care costs in the USA. Cost data have not been standard products of federally funded efficacy studies in the USA for the past 30 years. Yates (1997) has presented guidelines for psychotherapy researchers on how to collect cost data. Wolff, Helminiak, and Tebes (1997) illustrate the impact of different assumptions on cost estimates in mental health treatment research. Other relevant references are Knapp (1995) and Yates (1996). Research strategies to examine the amount of therapeutic effort required to obtain specific outcomes have been available for some time in the psychotherapy research literature (e.g., Howard, Koptka, Krause, & Orlinsky, 1986; Kopta et al., 1994).

3.10.5.1.4 Mediator's model

The crux of a model proposed by Clarke (1995) is to use IV experimental methods to examine crucial generalizability (EV) questions about an interventions' outcomes. For example, a study design could include two or more intervention conditions distinguished mainly by the degree to which an intervention is implemented as specified in its manual. The essence of Clarke's (1995) model is to use IV methods to evaluate the effects of several potential mediator variables on the outcomes that can be achieved with an intervention. Examples of relevant mediators are the degree to which therapists adhere to the structure of a therapy as specified in its manual, heterogeneity of the patients treated, and the adjunctive therapeutic context in which an intervention is provided (e.g., used as a stand-alone intervention vs. included in an intervention package).

3.10.5.2 Examples of Efficacy + Effectiveness Intervention Studies

This section illustrates the use of the concepts of IV and EV to evaluate intervention studies. Two highly regarded US studies that were designed to meet both IV and EV aims are reviewed: Drake, McHugo, Becker, Anthony, and Clark (1996) and Schulberg et al. (1995). The main intent of each review is to illustrate how the concepts that are the focus of this chapter can be applied to help determine the conclusions that can validly be drawn from an intervention study. The reviews obviously are not complete or definitive evaluations of either study.

3.10.5.2.1 Schulberg et al. (1995)

The investigators' interest in integrating IV and EV considerations in a single study is evident in the study's two main aims. One aim was to compare the outcomes of a type of psychotherapy and a medication when used to treat depression in patients who were being seen in general medical clinics, not psychiatric settings. Both of the interventions were tested previously in randomized controlled studies and found to be efficacious for depression in psychiatric outpatients. A second aim was to compare the effects on depression of each of the two tested interventions with the effects of a third intervention of "usual care," that is, treatments of the type typically provided to depressed patients by doctors in primary care settings.

Central IV features of the study were: random assignment of patients to all three treatment conditions, use of sample selection procedures to identify patients who met standard psychiatric diagnostic criteria for depression, and outcome analyses on an intention-to-treat sample. IV and EV were simultaneously enhanced by other methods. The same study protocol was implemented concurrently at four primary care clinic settings. Procedures were used to help ensure that the psychotherapy was conducted in ways consistent with its manual but that also were minimally intrusive into the conduct of the therapies. Central EV features of the study were: it was conducted in primary care settings (although all four settings had academic affiliations), outcome data were obtained from patients who were randomly assigned to usual care, and the natural course of the usual care condition was preserved as much as possible.

A noteworthy EV threat was substantial preinclusion attrition of eligible subjects due to refusal to participate and other reasons. An IV threat was that therapists were "nested" in a treatment condition. That is, the medical professionals who provided usual care were not the same professionals who provided the psychotherapy intervention or the pharmacological intervention. Thus, better outcomes of the previously tested (efficacious) interventions compared to usual care could not be attributed validly to the therapies *per se*. Findings of this type were, in fact, obtained. However, it can be argued that the confounding of therapists and treatments does not pose an important IV limitation to this particular study. Rather, the confound enhances the generalizability of findings to standard practice (EV) because in the public sector, primary medical care providers are not the same as those who provide specific forms of psychotherapy for depression or those who specialize in psychopharmacological treatments for depression.

3.10.5.2.2 Drake et al. (1996)

Drake et al. (1996) integrated IV and EV methods in a study designed to examine interventions of a very different type from those examined by Schulberg et al. (1995). Their main aim was to compare two vocational programs for individuals with severe mental disorders (SMD) such as schizophrenia. Drake et al. described the interventions as differing in two primary ways. One intervention was provided by a professional rehabilitation agency external to the mental health clinics where individuals with SMD were treated; the other was integrated with mental health services and provided at the clinics. A second difference was in the structure of the interventions. The external intervention ("group skills training," GST) started with three months of pre-employment skills training; the mental health clinic intervention ("individual placement and support," IPS) started immediately with job placement activities.

The central IV feature of the study was random assignment to each of the intervention conditions. A key EV enhancement design feature was that each intervention was concurrently tested at two sites. However, the full EV value of the multisite design was compromised because GST staff who had central training roles overlapped at the two GST sites. Also, the GST and IPS interventions each were conducted at different sites. Thus, as the authors point out, interventions and sites were confounded. This type of confound notably compromises IV, that is, the confidence with which outcome findings can be attributed primarily to interventions.

The study illustrates that sample selection criteria can simultaneously increase the homogeneity of a study sample and enhance EV. The inclusion and exclusion criteria constitute minimal, yet realistic, qualifications for SMD clients to receive vocational interventions (e.g., lack of noteworthy memory impairment; clinical stability as indicated by not being hospitalized for at least one month; unemployment for at least one month but interest in employment). The potential subject EV enhancement associated with the sample selection criteria was reduced by another procedure, a "prerandomization group experience." SMD clients who were interested in participating in the study were required to attend a minimum of four weekly research induction group sessions. One purpose of the prerandomization group attendance requirement was to ensure that potential participants were "motivated" for the project interventions.

Prerandomization and pretreatment "orientation" or "stabilization" phases are sometimes used in mental health intervention research, particularly with populations in which high treatment failure and/or dropout rates are expected, such as drug abusers. EV is one trade-off for the use of such procedures. On the other hand, the procedures can have an IV advantage. They can create samples of individuals who are most likely to respond to an intervention, thereby yielding findings on its efficacy with individuals hypothesized to be most responsive to it. One potential risk is that the sample will consist of individuals who are likely to benefit from many incidental life/environmental experiences and who, therefore, might not need the study interventions to achieve its targeted outcomes. The foregoing IV threat can be offset by the inclusion of a placebo control intervention of some type in the design.

Drake et al. (1996) also illustrates the critical impact on a study's CV, IV, and EV of the methods used to operationalize the interventions. The study report does not indicate if the interventions were specified in manuals or the type of training that counselors received before implementing them for the study. A related threat to the CV of the interventions and, thus, to the IV of study findings, is that the methods used to evaluate the success of the operationalization of the interventions (i.e., counselor adherence to GST and to IPS) are described too vaguely to evaluate. An additional IV threat is that it is not clear from the report if the IPS intervention was always provided by a counselor other than a client's SMD therapist. This is an IV consideration because the GST interventions were always provided by someone other than the client's SMD therapist.

One point illustrated by the preceding intervention-related aspects of the study is that the less clear and complete the description of methods used to implement interventions is, the less possible it is to evaluate their CV and, consequently, the IV of outcome findings. Thus, the public health significance of findings cannot be evaluated confidently. In turn, study findings can have less impact than they otherwise might.

An additional IV threat due to intervention procedures was site differences in the implementation of both interventions. The investigators intervened at one of the sites to correct deviations from the IPS model. However, the corrective attempts were not notably effective. The implementation of IPS is described as "weaker" at one site. Also, the GST counselors "concentrated their efforts" in one of their sites.

The study findings highlight the crucial importance to IV of intervention implementation procedures (intervention CV). In some analyses, the interventions differed on the major outcome variable (employment), favoring IPS; in others, the interventions did not differ. Interpretation of mixed findings about interventions' comparative effects is seriously compromised when the intervention CV is either poor or difficult to evaluate from information provided in a study report.

The foregoing review of Drake et al. (1996) from the perspective of IV and EV threats might seem inconsistent with the fact that it is widely regarded as one of the best IV + EV mental health intervention studies available. If it is assumed that the preceding IV and EV analysis itself is valid, what might be concluded? One conclusion is that difficulties maintaining the CV of interventions in studies that are done in natural settings to enhance EV can be costly in terms of IV. In turn, this analysis suggests that a cost-effective use of resources in high EV studies is to invest in methods that achieve and maintain the CV of interventions.

3.10.6 A CONCLUDING OBSERVATION

IV and EV considerations, and the related efficacy vs. effectiveness debate, highlight two vital applied aims of intervention research. The aims are: (i) to obtain findings that can be used directly and quickly in public mental health delivery systems, and (ii) to obtain findings that can markedly improve, ideally revolutionize, the effectiveness of treatments available in the public health sector. Both aims have clear public health significance. Aim (i) is most consistent with using designs and methods that are firmly tied to contemporary constraints on clinical practice in "real world" settings and obtaining findings that can affect practice in the short run. Aim (ii) is consistent with using scientific methods that are most likely to foster discovery and methods that can rule out rival interpretations of obtained covariation between interventions and outcomes. Immediate generalizability to current practice of findings from aim (ii) studies cannot be a central criterion of their public health significance.

The efficacy vs. effectiveness debate no doubt was partially fueled by efficacy researchers' frustration. Many of them observed that years of findings from high IV studies that support the value of certain types of psychotherapy (Task Force on the Promotion and Dissemination of Psychological Procedures, 1995) were eschewed by many who focused on the EV of those studies. Also, emphasizing EV limitations of well-done, high IV studies can impede implementation of tested therapies in public sector settings. By default, then, the use of untested, "treatment as usual" interventions is supported and maintained. This is the current situation in the USA.

A partial antidote to the preceding problem, a serious problem from the public health standpoint, was suggested by Kazdin et al. in 1986. Their suggestion is consistent with a point made earlier in this chapter. Mental health intervention research advances since the late 1980s include methods to systematically train therapists in therapies with demonstrated efficacy, and to evaluate the skillfulness that therapists attain from the training. Many therapist training and adherence assessment research methods generalize directly to public sector therapists. Thus, rather than look at findings from high IV studies and ask the therapist EV question: "Does the study provide evidence that therapists in the public health sector will be able to get the same results?," the question could be refocused: "Does the study provide methods that enable therapists to be identified and trained to get the same outcomes in public treatment settings?"

ACKNOWLEDGMENTS

Preparation of this chapter was supported by National Institute of Mental Health Grant K02 MH01443 to Karla Moras. Sincere thanks are extended to those who provided consultations, comments, or other contributions to the preparation of the manuscript: Phyllis Solomon, Elizabeth McCalmont, Christine Ratto, Heidi Grenke, J. R. Landis, and Jesse Chittams.

3.11.1 INTRODUCTION

The US National Institute of Mental Health blueprint for improving services (NIMH, 1991; Attkisson et al., 1992; Lalley et al., 1992; Mechanic et al., 1992; Steinwachs et al., 1992) broadened and clarified the scope of mental health services research. New and experienced investigators trying to understand mental health services research, however, may find it hard to comprehend the multiple perspectives on the field and how seemingly disparate research agendas contribute to a unified body of knowledge. Nevertheless, a unified view of the field can be gained by reflecting on key constructs and the causal paths that connect them.

Mental health services research is inherently multidisciplinary, drawing from clinical psychology, psychiatry, health economics, epidemiology, sociology, political science, social work, nursing, pharmacology, pharmacy, general medicine, and public health. This multidisciplinary character is reflected in the authorship of this article, including two clinical psychologists, an urban planner, and a health economist. Many clinical psychologists are contributing to mental health services research and more are needed.

In spite of great heterogeneity of methodology, all of services research can be viewed as examining some aspect of a nested system of causal processes that influence the mental health and well being of society. At the inner core are the effects of specific services on individual users of these services. These effects are contained within the broader effects of the way services are organized into local or other end-user service systems, how services are financed, and how these services systems impact relevant target populations. These effects of the organization and financing of services are in turn influenced by policy innovations of local, state, national, and international scope that influence the functioning of local service systems. These three domains of effects correspond to different types of services research: cost-outcome studies, service system studies, and policy studies.

The inner core of services research, cost-outcome studies, in turn grew out of an established tradition of clinical efficacy research utilizing the randomized clinical trial. The Agency for Health Care Policy Research of the US Government, in an attempt to foster services research, popularized a distinction between efficacy and effectiveness research in the evaluation of medical technologies (Salive, Mayfield, & Weissman, 1990). Efficacy studies evaluate the effect of an intervention under optimal conditions, when implemented by highly skilled clinicians using comprehensive treatment protocols under expert supervision, and where the intervention is usually delivered to patients with a single, well-defined disorder. Effectiveness studies complement the findings of efficacy studies by evaluating interventions in conditions, settings, and target populations that reflect the usual circumstances in the delivery of services, often giving attention to long-term effects of treatments on both costs and outcomes. The term "cost-outcome" is used to avoid confusion between "effectiveness" studies and "cost-effectiveness" studies, since the latter use a specific subset of cost-outcome methods.

Cost-outcome research remains conceptually and methodologically linked to efficacy research. The refinement of clinical trial methodology over several decades has established a useful state of the art that includes random assignment to treatment, appropriate blinding, complete follow-up with "intent-to-treat" analyses, and improved statistical handling of longitudinal data with missing or unevenly spaced measurement occasions, as discussed in Chapter 3, this volume. Cost-outcome studies involve the extension and improvement of clinical trials methodology necessary to address broader questions of generalizability, accessibility, acceptability, cost, and long-term outcome of interventions.

This chapter contrasts efficacy research and the three types of services research on several dimensions, and gives examples of each. These research models differ on a number of features: (i) their typical unit of analysis; (ii) the outcomes of primary interest; (iii) their typical design strategies; (iv) the independent variables usually experimentally controlled or sampled by the investigator; and (v) the hypothesized causal variables of greatest interest. Table 1 summarizes these features for each of the four models. As each model is discussed it will illustrate the causal pathways of usual interest, as portrayed in Figures 1 to 4.

3.11.2 EFFICACY RESEARCH

Efficacy studies examine the effects of a well-defined treatment or other service on the clinical and rehabilitation outcomes of individual recipients of care. Figure 1 is familiar to clinical trials investigators and shows the key groups of variables and causal paths of primary interest. Fifteen causal paths, numbered A1 to A15, encompass the scientific focus of efficacy research.

The ultimate outcomes of efficacy studies are reductions in illness symptoms, changes in behavior, or improvements in skills. Outcomes are usually measured over weeks or months rather than years. The unit of analysis is the person who consumes services. The typical study will compare an innovative treatment to either a placebo, an accepted "standard" treatment, or some other control for attention and expectation effects. Double-blind controls are employed to minimize bias that might be caused by expectation effects on outcomes and on judgments of outcomes. When the blind is likely to "leak" or is otherwise impossible to maintain, blinding of interviewers and raters is sometimes attempted as a partial effort to reduce bias.

The causal chain of primary interest is usually causal path A10, the effect of the implemented service on ultimate outcomes. Investigators may also be interested in the mediation of this effect through the use and "receipt" of service and through proximal outcomes. Thus, several aspects of the whole cascade of effects A1 to A8 may be examined. Even more broadly, efficacy studies may take account of the characteristics of the person at baseline such as diagnosis, severity of disability, history of treatment compliance, and stage of illness in order to understand their modulation of intervention effects (A11 and A13). Similarly, the effects of the person's preservice life context (e.g., homelessness, poverty, social support system, entitlements, insurance coverage) may be examined, along with life context during and after service (A14 to A15). In efficacy studies,

Hypothesized causal variables of interest	Service delivery and receipt	Service delivery and receipt	Local system organization, financing, management, and innovation.	Policy innovation above the local level

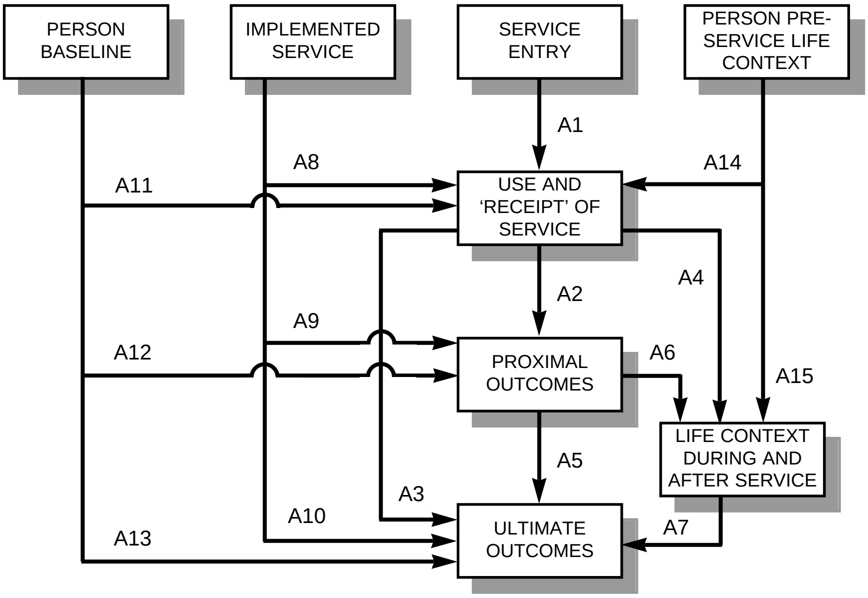

Figure 1 Efficacy studies.

however, the goal is usually focussed on causal path A10 while other causal paths are viewed as "nuisance" effects or "artifacts" that threaten a valid assessment of path A10.

The typical design strategy is the randomized trial. The design of efficacy studies typically emphasizes the "internal" validity of the estimate of the effect of a treatment, taking care to exclude alternative explanations for the observed effects, such as baseline or post-attrition differences in persons receiving different services.

Efficacy studies may focus on the mechanism of action of the intervention. Mechanism can often be inferred from analyses of "intermediate" variables that may account for the service effect, such as service use and "receipt" (e.g., medication or psychosocial treatment adherence, regularity of appointments, attitude toward the services), proximal outcomes (e.g., learning a communication skill, immediate symptomatic response to a medication), and changes in living setting or social support system resulting from the intervention.

The quest for internal validity and adequate statistical power often leads to considerable sacrifice of "external" validity, or generalizability. Service entry by study subjects is taken as a given, and usually little effort is made to relate the characteristics of the subject sample to those of the target population. Indeed, the usual efficacy study purposely employs narrow criteria to produce a homogeneous sample of subjects with few "distracting" sources of variance, such as comorbid illnesses, that may be quite prevalent in the population likely to receive the innovative intervention. Subjects are recruited from some convenient source that can yield enough subjects who qualify and will consent, making the assumption (usually unstated and unexamined) that the clients entering screening represent the target population on the dimensions that matter for generalization.

3.11.2.1 Examples of Efficacy Research

The National Institute of Mental Health "Treatment Strategies in Schizophrenia" cooperative study is an example of a late-stage, complex efficacy study. Schooler, Keith, Severe, & Matthews (1989) and Schooler et al. (1997) compared maintenance treatment strategies for people with a recent schizophrenia relapse whose family is in the picture. The study assessed the impact of dose reduction of antipsychotic medication and family treatment on relapse and rehospitalization during maintenance treatment (paths A1 to A15 in Figure 1). Standard dose medication was compared to continuous low-dose or targeted treatment, in which active medication was used only upon incipient signs of relapse. A widely studied and effective type of family intervention was compared to a much less intensive family intervention in the context of assertive medication management and ongoing supportive assistance to patients and families. It was hypothesized that the more intensive family intervention would make the conservative low-dose and targeted medication strategies more effective, perhaps as effective as standard-dose but with less burden from medication side-effects. The three-by-two design thus produced six treatment combinations, and the interaction between dosing strategy and family intervention level was of primary interest. The investigators found that both continuous low-dose and targeted medication increased the use of "rescue" medication and the risk of symptomatic relapse, but only targeted treatment increased hospitalization compared to standard-dose medication. The two family interventions showed essentially no differences in effectiveness, and family intervention did not interact with dose effects. There were two important policy implications of the findings: (i) targeted treatment, which had been advocated by some investigators, should not be adopted as a standard maintenance strategy, and (ii) the intensive family interventions that had been shown in previous research to be effective compared to no family intervention are more intensive than needed when provided in the context of good continuity of maintenance treatment and initial education and support of family members.

Like most efficacy studies, however, the primary focus was on mechanism of action rather than policy generalization. All sites were university-affiliated clinics, not sites picked to represent the "usual" circumstances of schizophrenia treatment. The design limited the ability to generalize to patients who did not reconstitute within six months of their most recent psychotic episode.

Nevertheless this study also had some features of cost-outcome research. "Ordinary" clinicians were recruited and trained as family clinicians, the study was carried out in five sites allowing a test of whether the findings generalized across site, and costs were assessed, although cost analysis was not part of the original design.

The methodology for efficacy research is well developed and relies heavily on the randomized clinical trial. The field reached a reasonable consensus on efficacy methodology in clinical psychopharmacology in the 1970s, and in psychotherapy efficacy research since the mid-1980s.

3.11.3 COST-OUTCOME RESEARCH

Cost-outcome studies of mental health services expand the scope of efficacy research to address key questions related to the effects of mental health services delivered in typical care settings. Figure 2 illustrates the expanded causal paths examined in cost-outcome studies. These include the same causal paths (A1 to A15) from efficacy studies (Figure 1), but include additional factors not addressed in efficacy trials (B1 to B21). Access to services is often examined in cost-outcome trials (Paths B1 to B9), and cost-outcome studies always measure the use and cost of services, including services other than the experimental interventions themselves (B10, B14, and B15).

The ultimate outcomes of cost-outcome studies are broad, including clinical outcomes (illness symptoms, side effects), rehabilitative outcomes (productivity), humanistic outcomes (life satisfaction, family psychological burden), and public safety outcomes (disruptive behavior, assaultiveness, suicidality, criminal behavior). Cost-outcome studies also may consider determinants of outcomes resulting from a wider range of causes including program case mix, consumer life context, and service cost/payer mix (B3, B7 to B9).

More importantly, perhaps, there is a fundamental shift in the perspective on outcomes in cost-outcome studies (Hargreaves, Shumway, Hu, & Cuffel, 1997). The ubiquitous fact of multiple, poorly correlated outcomes in mental disorders creates a problem that cannot be ignored in cost-outcome studies, since policy conclusions regarding the choice of alternative interventions depend on the relation of overall cost to overall outcome.

Different approaches to integrating outcomes are reflected in four different types of cost-outcome studies Cost-minimization studies examine only costs, in situations in which outcomes are known or assumed to be equal (B10, B14, B15). Cost-benefit studies focus on outcomes that can be monetized, such as labor force productivity, and analyze either cost-benefit ratios or net benefits (benefits minus costs) (B11, B16, B17). Cost-effectiveness studies leave outcomes in their natural units, and cost-effectiveness ratios are computed either on single outcomes (e.g., cost per suicide prevented) or on a global or integrated outcome score (e.g., cost per one unit of level-of-functioning score gained) (B12, B18, B19). Cost-utility studies utilize cost-utility ratios, where utility is a preference-weighted unitary outcome (e.g., cost per quality-adjusted life year gained) (B13, B20, B21). All of these studies are comparative—no intervention is "cost-effective" by itself. The cost-outcome performance of an intervention is always judged against a policy-relevant standard, such as treatment as usual. Cost-outcome ratios are not needed to compare interventions when the less costly intervention produces better outcomes. When an innovation is both more expensive and more

effective than standard care, a common type of cost-outcome ratio compares the differential cost per differential outcome gained by the innovation compared to standard care.

Cost, as a consequence of an intervention, has its own measurement technology that has been carefully worked out in econometrics and health economics (Drummond, Brandt, Luce, & Rovira, 1993; Drummand, Stoddard, & Torrance, 1997; Sloan, 1995). Economic theory provides the conceptual underpinning of cost estimation methods. In a theoretically ideal competitive market, goods and services are exchanged at prices that reflect their true value. In the real world market quality varies, and in health care the operation of a free, competitive market is impaired because buyers and sellers have inadequate information, and because third-party payers and government regulation also introduce market distortions. The theory of welfare economics provides an alternative way to estimate the true value of goods and services when market pricing is not accurate. Under these circumstances the true value is estimated by considering the "opportunity cost" of resources. This value estimate, called a "shadow price," is the value of a resource were it to be used for its "next-best" purpose.

Economists also developed the concept of "societal" cost to describe a cost perspective of an entire economic system, without regard to who pays the cost. Societal cost is accepted widely as a standard reference method in cost-outcome research (Drummond et al., 1997). Most policy questions, however, also need to be informed by information about cost burdens to particular payers. For example, if a new intervention results in the same cost as usual care (from a societal perspective), but shifts the payment burden from the state and federal government to local government, or from government to the ill person's family, the payer information is important. Economists call shifts in payer burden a "distributional effect" of the innovative intervention, since it distributes the grief in a new way.

The difference in societal cost of two intervention strategies is the difference of the value of resources consumed or lost. Resources consumed (e.g., treatment activities) are called "direct" costs, while resources lost (e.g., time prevented from working, which produces resources) are called "indirect" costs. The amounts of resources are measured in natural units (hours of psychologist time, days of hospitalization), but values are assigned to these resource units by a separate process. In this way, questions about the accuracy of methods for measuring resource use can be examined separately from questions about the appropriateness of the values assigned to each type of resource.

Seven types of cost elements are often considered when planning mental health cost-outcome research: mental health treatment, physical health care, criminal justice procedures, social services, time and productivity of the patient and of family caregivers, other family costs, and sources and amounts of patient income. Different interventions and target populations vary greatly in the relative emphasis that needs to be given these seven types of cost. The most accurate measures of consumption and the most careful estimates of value are usually reserved for the most commonly used resources, especially the new activities introduced in the innovative intervention being studied.

Expert judgment is required to choose an appropriate balance of methods and to apply them skillfully. In most situations neither health economists nor clinical investigators can do it alone, and effective collaboration is required. Hargreaves et al. (1997) provide an introduction to cost-outcome methods for mental health research, designed to prepare noneconomist investigators for this type of collaboration.

The unit of analysis in cost-outcome studies is still the person, but attention is given to the person as a member of a target population, the paths from target population membership to service, the generalization of the findings to this target population, and even the impact of service provision or access policies on the whole target population.

The typical design strategy is the randomized cost-effectiveness trial focused on both internal and external validity, comparing a service innovation to standard services, and estimating the impact on the total target population as well as individual members of that target population. Ideally the size and character of the target population is estimated, and a random sample is invited to participate in the study. More often, a series of analyses tracks the biases in selection from target population, to potential subject pool, to recruited subject sample, to analyzable subject sample.

In these decision-oriented studies, certain "standard" features of efficacy trials, such as double-blind conditions, may be avoided in order to enhance external validity. For example, an open study does not require sham procedures such as unnecessary blood samples, or active placebos that mimic side effects, both of which may obscure the relative acceptability of services being compared. This may increase risks to internal validity, as when an open study allows rater bias and alters client expectation effects. These problems should not be ignored, although they are less troublesome when conclusions hinge on long-term social and vocation functioning improvement rather than short-term symptom improvement.

Despite the broader scope of cost-outcome studies, several types of variables are taken as given or set by the investigator, including the service model, the character of the target population, the consumer's baseline clinical characteristics and life context, and preservice utilization and costs. In service system research, by contrast, it will be seen that investigators may view these variables as outcomes.

3.11.3.1 Examples of Cost-outcome Studies

A study of assertive community treatment was an exemplary cost-benefit study (Stein & Test, 1980; Test & Stein, 1980; Weisbrod, 1983; Weisbrod, Test, & Stein, 1980). In this study the experimental treatment was applied for 14 months. Subjects in the experimental program had less time in the hospital, more time in independent living situations, better employment records, increased life satisfaction, decreased symptoms, and improved treatment adherence. Family and community burden did not appear to increase (A1, A3, A4). Societal cost was found to be slightly lower in the experimental treatment when wages earned were considered monetary benefits and welfare support was considered a cost (B10, B11, B14 to B17). Thus, the innovative program showed both an economic advantage and a psychosocial advantage.

Research on assertive community treatment (ACT) for persons with severe mental illness is the strongest and most coherent body of cost-effectiveness investigation in mental health. More than a dozen additional randomized trials of ACT were published from 1986 to 1996 and the findings have been critiqued and summarized in many reviews (Bond, McGrew, & Fekete, 1995; Burns & Santos, 1995; Chamberlain & Rapp, 1991; Hargreaves & Shumway, 1989; Olfson, 1990; Rubin, 1992; Santos, Henggeler, Burns, Arana, & Meisler, 1995; Scott & Dixon, 1995; Solomon, 1992; Test, 1992). Studies in the 1990s utilize stronger usual care conditions, reflecting the widespread adoption of linkage case management in the USA (Burns & Santos, 1995; Randolph, 1992). These studies are refining understanding of the conditions and target groups in which assertive community treatment is cost-efficient or has such superior outcome in spite of increased cost that it can be considered cost-effective relative to available service alternatives.

A randomized cost-effectiveness study of the atypical antipsychotic clozapine for persons with schizophrenia was carried out by Essock; (Essock, Hargreaves, Covell, & Goethe, 1996a; Essock et al., 1996b). It featured a complete enumeration of clozapine-eligible patients in an entire state hospital system, and a mix of random and purposive selection of members of the eligible pool to be offered study entry during a time when clozapine was rationed by the state hospital system and study participation was essentially the only route of access to clozapine treatment (B1 to B9). Study subjects were randomized to clozapine or usual antipsychotic medication in an open study (A1 to A15). An effectiveness and cost evaluation was carried out over two years of treatment (B10, B12, B14, B15, B18, B19). Clozapine showed fewer side effects with some advantage in reduced restrictiveness of care and reduced assaultive or disruptive behavior. In this long-stay state hospital patient group (mean length of their hospital episode was over eight years) no effect was seen on time from study entry to hospital discharge. In contrast, once discharged, clozapine patients were much less likely to be readmitted, resulting in saved hospital days. Full cost analyses have not been completed, but saved hospital costs may fully offset the higher price of the novel antipsychotic medication plus the increased cost of community care when patients are out of the hospital. This study illustrates how the results of an effectiveness trial comparing a new treatment to usual practice can be more conservative than an efficacy trial comparing a novel medication to a single alternative. Previous efficacy trials had shown larger effects on symptom improvement, typically in patients who were in an acute illness exacerbation, not the relatively stable but still symptomatic long-stay state hospital patients who showed lower baseline scores on symptom scales.

A study by Henggeler, Melton, and Smith (1992) illustrates how research can have an intermediate position between efficacy and cost-outcome research. Henggeler studied "multisystemic therapy" (MST) as an intervention for serious juvenile offenders and their multiproblem families. Yoked pairs of qualified subjects randomized to multisystemic therapy or usual services were referred by the South Carolina Department of Youth Services. Endpoints included family relations, peer relations, symptomatology, social competence, self-reported delinquency, number of arrests, and weeks of incarceration. Compared to youths who received usual services, youths who received MST had fewer arrests and self-reported offenses and spent an average of 10 fewer weeks incarcerated during a 59-week study period. Families assigned to MST reported increased family cohesion and decreased youth aggression in peer relations. Detailed cost analyses were not reported in this initial publication. This is one of the first controlled trials of interventions with this difficult target population to show significant beneficial outcomes and clinically important effects. The success of the intervention plausibly is related to its addressing each of the major factors found in multidimensional causal models of antisocial behavior in adolescents (Henggeler, 1991).

This study can be considered efficacy research in that it was delivered under close supervision of those who designed the intervention, and further evidence is needed that its effectiveness can be maintained when the intervention is taught and supervised by others. In addition, the statistical power of the initial study is limited, so while large and statistically significant effects were observed, effect size in the population still needs to be estimated more accurately before basic efficacy can be considered to be established. Features more like cost-outcome research include the construction of a subject pool that is plausibly representative of an important target population, and (except for service supervision) the intervention reflects much of the reality of providing such services in ordinary settings of care. The study can also provide preliminary information about the cost of the intervention and the cost savings that may result from its effective implementation.

The methodology for cost-outcome studies is a combination of cost-effectiveness methods from health economics, mental health epidemiology methods, and randomized controlled trial methods, applied to intervention processes that sometimes take place over several years. The merger seems to require ambitious and expensive multidisciplinary studies, but that conclusion is probably incorrect. The new investigator can work in this area by learning the methods and gathering appropriate consultants and collaborators. A workable state of the art is reasonably well advanced and accessible (Drummond et al., 1997; Hargreaves et al., 1997; Knapp, 1995; Sloan, 1995; Yates, 1995).

3.11.4 SERVICE SYSTEM RESEARCH

Research on local mental health service systems examines the effects of organization, financing, and service delivery mechanisms on utilization of services, costs, outcomes, cost-effectiveness, and community prevalence. The object of study, mental health service systems and community outcomes, are of broader scope than phenomena affecting the relative cost effectiveness of a circumscribed group of services for a specific problem or disorder. Therefore, cost-outcome research on mental health systems draws on economics, organizational sociology, epidemiology, and political science for explanatory theory and method. A mental health system serves an array of target populations whose service needs differ, yet these target populations also compete for many of the same services. Therefore it is reasonable to view system impact as its effect on a value-weighted sum of its impact on the prevalence of the array of mental disorders and their resulting impairments.

The ultimate outcomes in service system research are the prevalence and disability consequences of various mental disorders in the population. Intermediate outcomes include demand for mental health services, access and use of those services, and outcomes of those services. More broadly, the ultimate outcome is seen as the quality of the life of all members of the community, to the extent that it is affected by psychiatric disorders. Mental health systems and system managers work within a political, fiscal, and organizational context to focus service resources on high priority target populations so that the overall cost-effectiveness or cost-utility of the system is maximized.

Service system utility implies value judgments not only about trade-offs in outcomes for a particular target population, but trade-offs in the value of higher levels of functioning in one target population as against another. For example, after many years during which community programs were focused on improving the level of functioning of clients and families with serious life problems but who were not severely and persistently mentally ill, these values were called into question, and service programs shifted their emphasis to the latter group. While many factors influenced this change (Mechanic, 1987), including a rise in the relative cost of hospital care, the change also reflected an implicit value judgment that serving the severely and persistently mentally ill in the community was of overriding importance to the overall utility of the mental health service system. This implicit utility judgement could never be examined explicitly, because the complexity of the problem exceeded capacity to study it. An effort to identify the parameters of this problem may clarify the advances in theory and method needed to address such issues.

The system dynamics of prevalence, demand, utilization, and outcome can be seen as interacting with the service process, which in turn interacts with the system structure. Process and structure subsystems may experience innovation or innovation may be introduced experimentally. In either case, innovation can give the investigator an opportunity to learn something about causal phenomena in the system.

A simplistic view of system dynamics (Figure 3) is that different levels of prevalence cause different levels of service seeking behavior, that service seeking leads to utilization, that utilization influences outcomes for individuals, and these outcomes change prevalence and disability. Some variables of interest in each of these subsystems can illustrate the possibility for more realistic models.

Prevalence is used here to include not only the local prevalence of persons with psychiatric disorders and subgroups of such persons, but the distribution within these populations of living independence/freedom, productivity, homelessness, life satisfaction, public safety, and the societal cost of illness. These valued

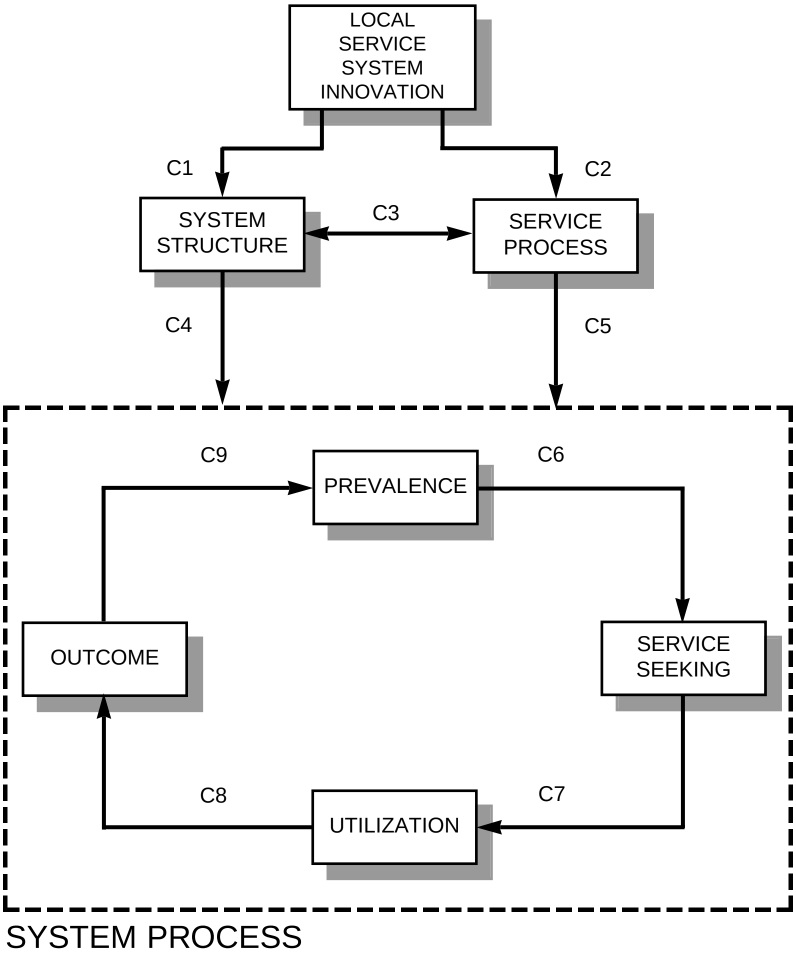

Figure 3 Service systems studies.

conditions and costs define the momentary utility of the human service system with regard to persons with psychiatric disorders. This utility can be influenced by effective human services. It can also be influenced by migration, system induced or otherwise. An innovation that incurs some marginal cost can be evaluated by comparing this cost to the change in utility that one is able to attribute to the innovation.

Priorities for various target populations and levels of disability are an unavoidable part of any definition of system utility. An egalitarian society aims to maximize cost utility without differential weighing of gender, age, socioeconomic status, ethnic group, residence location, or reason for disability. While real-world policy is formulated from narrower perspectives, it is useful for science to identify the larger impact of narrow policies. In the short term more modest research goals should be sought. Practical compromises may include restricting study samples to persons known by the service system to be in the target population, and considering only expenditures within the mental health system. This is a narrower perspective on target populations and cost than suggested for cost-outcome studies, in order to allow greater research investment to be focused on measuring a larger variety of intermediate effects and associated causes.

Service seeking results from experienced need and the lack of social supports (Alegria et al., 1991; Freeman et al., 1992), and is affected independently by economic conditions and job insecurity (Catalano, Rook, & Dooley, 1986). The need may be experienced by the ill person, by family members, or as a community response to illness-related disruptive behavior. Service seeking produces demand on each type of service provided in the system or seen as needed by each target population subgroup. There may be a pattern of over-capacity demand experienced by specific services, with demand-buffering patterns and consequent generation of secondary demand, that is, inappropriately high levels of care and lack of access to desired services. Cost-outcome and service system research should inform both providers and consumers about the relative value of alternative mental health services, enabling them to make informed choices about which services to supply or to consume.

Utilization is the actual amount of each type of service consumed by various subgroups of persons in the target population, and in some cases by other clients who compete for the same services. It is this consumption and its effects on outcome and cost compared to what would occur in the absence of service or with alternative services that are often the focus of research attention.

Outcome includes those changes in symptoms, functioning, life satisfaction, and public safety that result from the consumption of services. The strengthening of natural supports and the reduction of risk of relapse might be been as relevant outcomes. At the individual level these are the same variables as the prevalence conditions. Whether outcomes lead to changes in prevalence variables depends on the proportion of the target population that consumes appropriate and effective services, and the degree of offsetting changes that may occur in the rest of the target population.

The unit of analysis may be the individual for purposes of measurement although there is greater attention to the characteristics of the population from which samples are drawn. For example, service system research often attempts to make inferences about the effects of service system characteristics on mental health outcomes in the general population. In this regard, the unit of analysis can be the geographic area served by the local service system, particularly when the focus of study is aggregate statistics such as per capita rates of violence or suicide measured over time or across regions.

The causal chain of interest includes three broad aspects of local area service systems that are common sources of independent variables in service systems research. These are system structure, service process, and system innovation.

System structure includes a study of local system expenditures and expenditure decisions, the organization governance, networks, and environments, service system size, integration, and cohesiveness and local provider reimbursement policies, benefit eligibilities, risk-sharing incentives, and managed care strategies for monitoring and controlling the delivery of care.

Service process at the system level might be viewed as consisting of two types of variables: (i) service capacity mix (how many beds or slots of various types) and the unit costs of each type; and (ii) services integration methods such as linkage case management, assertive community treatment, entry and exit criteria, and treatment guidelines. For each service program or provider in the system one might examine management style, staff morale, and adherence to system-wide service delivery standards. Adequate measures of these aspects of the mental health delivery system need to be developed, especially such dynamic processes as eligibility criteria and service practices that shift in the demand-buffering process, or transient degradation of service capacity that may occur during rapid system change.

Local service system innovation can be viewed from a research perspective more as an event than a subsystem. Innovation, and indeed any change including financial disaster and dramatic downsizing, is of interest to the investigator because change offers the opportunity to study causal effects. This is particularly true when a similar change occurs or is introduced experimentally in a number of local mental health systems, allowing better strategies for distinguishing the effect of the change from other variations in system performance.

The typical design strategies that are employed in the study of local service systems draw from economics, organizational sociology, and epidemiology, in addition to traditional clinical research and cost-outcome research. Studies of the variability in local mental health policy often involve economic analysis of utilization and expenditure patterns across counties or other local geographical areas. Often system level changes resulting from imposed changes in conditions or local innovation facilitate naturalistic experiments, pre-post designs, or time series analyses that allow one to study the effects of these system changes on service seeking, use, and outcomes. States and the federal government in the USA are also seeking to learn from "pilot" innovation using experimental or quasi-experimental approaches, in collaboration with investigators.

The Substance Abuse and Mental Health Services Administration has sponsored a multistate experiment comparing two experimentally introduced innovations in local systems of care focused on homeless persons with dual disorders (severe mental illness and a substance use disorder). State mental health authorities were invited to propose pairs of sites to undertake a program to reduce homelessness among substance abusing persons with mental illness by increasing case management and housing supports. Both sites in each applicant state were to propose two specific innovations appropriate for their site: (i) methods for delivering augmented case finding and case management services, and (ii) methods to achieve increased system integration to enhance services for homeless persons with dual disorders. Site pairs were evaluated for their suitability for the demonstration and selected by reviewers. Selected pairs of sites received funding for initial engagement, case management, and follow-up of a comparable cohort of clients, while one site of each pair was randomly selected to receive additional "services integration" funding. Thus, this design addresses causal paths C1 to C5 and C6 to C8 in Figure 3, although it does not examine changes in the prevalence of this homeless subpopulation (C9). Preliminary results have been reported showing that the additional services integration funding augmented the effectiveness of services for the target population over and above the provision of augmented engagement and case management services (CMHS, 1996; Robert Rosenheck, personal communication, November 20, 1996).

Not all service system research requires a large budget. Some dramatic system changes occur with little warning but can be investigated retrospectively using time series methods. For example, Fenton, Catalano, and Hargreaves (1996) studied the impact of passage of Proposition 187, a ballot initiative in California mandating that undocumented immigrants be ineligible for most state-funded health services and requiring health providers to report persons suspected of being undocumented to the Immigration and Naturalization Service. Hispanic-Americans widely felt this as a racist initiative specifically directed at them. Though quickly blocked in court, publicity about the initiative and its level of support (passing in 50 of 58 counties) was hypothesized by the investigators to cause young Hispanics to avoid preventive psychiatric services (outpatient mental health treatment) putting them at risk for increased use of emergency services at some subsequent time. This hypothesis could be seen as involving causal path C6 in Figure 3, though (to anticipate) it also reaches up to causal paths D5 and D7 in Figure 4, discussed in the Policy Studies section.

The investigators analyzed data on weekly initiation of public outpatient mental health episodes and psychiatric emergency service contacts in the City and County of San Francisco for 67 weeks before and 23 weeks after the date of the election. Young Hispanics were compared to young non-Hispanic whites using Box-Jenkins time series methods. Initiation of outpatient services by young Hispanics dropped significantly the week of the election and remained low compared to use by non-Hispanic whites.

To refine their hypothesis of a delayed effect on emergency services use, the investigators examined the "natural" variation in the initiation of outpatient mental health services and its relation to emergency service episodes. Low rates of outpatient initiations were correlated significantly with high levels of emergency service episodes six weeks later in the client population as a whole. Looking at emergency use by young Hispanics (controlling for use by young non-Hispanic whites), the investigators found significantly higher use of emergency services six weeks after the election. Analyses of older populations showed neither of these effects of the election. Thus, the effect was specific to the typical age range of undocumented Hispanic residents. For a relatively non-technical introduction to time-series methods see Catalano and Serxner (1987), and for more detail see Box, Jenkins and Reinsel (1994).

Time-series analysis also can be used to test hypotheses about service system policies. In a provocative study, Catalano and McConnell (1996) tested the "quarantine" theory of involuntary commitment, which asserts that involuntary commitment of persons judged to be a danger to others reduces violent crime—a theory vigorously challenged by civil libertarians. This hypothesis could be seen as encompassing the entire causal loop in Figure 3 of paths C6 to C9.

No one has much enthusiasm for carrying out an experimental test of this theory. The investigators tested the specific hypothesis that the daily incidence of reported assaults and batteries by males is related negatively to the incidence of involuntary commitments of males as a danger to others during the preceding two days—the more men committed, the fewer the subsequent arrests. Involuntary commitments on the day of the reported assault were omitted because the direction of causality is ambiguous. Using data from the City and County of San Francisco for 303 days, the investigators carried out a time-series analysis that supported ($p < .05$) the conclusion that increased commitment of men judged a danger to others reduces the incidence of assault and battery offences. Score: paternalists, 1, civil libertarians, 0. The discussion continues.

These three examples illustrate that service system changes of interest may be introduced intentionally (a new intervention for homelessness), or arrive as unpredictable exogenous shocks (Proposition 187), or arise from endemic variations that all organizations exhibit by virtue of their inability to behave with perfect consistency over time (variation in the number of involuntary commitments). This third type of variation is of particular interest to managers of mental health systems. They manage organizations to minimize this inconsistency, but theories of rational management as well as common sense suggest that the effort to do so

should cost less than the benefit of greater standardization of output. Managed care is the health system's version of scientific management, and one of its consistency tools is the treatment guideline or algorithm.

Research on the impact of treatment guidelines and algorithms is an important and growing area of service systems research. Suppose an investigator wishes to test the hypothesis that new treatment guidelines improve outcomes while containing cost. The guidelines might be both restrictive (specifying when a procedure should not be provided even when sought by the client) and prescriptive (specifying when a procedure should be recommended proactively when the client fails to seek it). It is interesting to consider the design issues posed by this research goal.

To test the investigator's hypothesis for a particular disorder, the investigator needs to identify or articulate the relevant restrictive and prescriptive guidelines. Identifying potential health risks and benefits from these guidelines compared to usual practice will guide the choice of outcomes and the length of observation needed to detect each outcome.

In implementing the study the investigator needs to demonstrate that the implementation has induced optimal or near-optimal guideline adherence by health care providers, has induced it relatively rapidly, and has maintained adherence consistently over the long haul. This will usually require prompting and monitoring techniques, which are part of the cost of the intervention being tested. The investigator also will want to demonstrate that the usual-care control condition had not undergone similar practice changes. Another concern is that guidelines may alter the detection of the targeted health conditions. The investigator needs a way to determine whether detection of the target conditions is altered in either experimental or usual care. Given these possible diagnostic screening effects, the investigator has the problem of designing an unbiased way to select "tracer" patients to assay outcomes in both experimental and control conditions.

These competing threats to validity demand well-articulated hypotheses and carefully chosen design compromises. Rather than randomizing patients, an investigator may decide to randomize clinician practices or clinical sites to experimental and usual-care conditions. Cluster randomization often is used in educational research, where an innovative teaching method is randomized to teachers or classrooms (Murray et al., 1994). Thus, individual subjects are nested within the unit of randomization. This does not preclude examining individual baseline characteristics in the analysis, however.

Power is limited by the number of units randomized, but error variance is also reduced (and power increased) by increasing the number of subjects within each randomization unit. For each of the primary outcome measures, the power analysis informs the investigator about trade-offs between the number of randomization units and the number of subjects within each unit. The efficiency of the design will further depend on the cost of adding units versus the cost of adding subjects within units. Feasibility and cost constraints often limit the number of randomization units to a smaller than optimal number. Under these circumstances the investigator may be able to gain power if between-unit outcome variance can be reduced by using covariates (Raudenbush, 1997).

As these considerations illustrate, the important design issues in service systems research are the same as in efficacy and cost-outcome research. Intervention effects are most easily understood when interventions are introduced experimentally with some form of random assignment. Multistep causal processes can be studied most effectively with a clear theory about intermediate causal pathways and effects, and ways to demonstrate that expected intermediate effects are produced and potential confounding effects are avoided.

3.11.5 POLICY RESEARCH

National and state reform of the organization and finance of mental health systems is a major research issue in mental health economics. Financing processes and incentives are changing rapidly. Local government is being given increasing responsibility for providing mental health services for persons with severe mental illness, either through direct operation of the services or through contracting with the private sector. Mental health services research is examining the impact of these economic forces and changes at both the national and local levels. Figures 3 and 4 illustrate the linkage between national and state policy decisions and their effects on local service system innovation and adaptation. Research focuses on the impact of these changes on access to care, organizational adaptation, outcomes for the most vulnerable target populations, costs, and the changes in cost burden to various payers.

Figure 4 suggests that policy initiatives by national and state government agencies offer a useful research focus for the mental health services investigator. Examining the link between national/state initiatives and the cost-effectiveness of services at the client level involves "long-chain" causal paths in the extreme. Therefore, research designs need to be thoughtful and realistic. Some research questions may focus simply on the link from national/state policy initiatives to local service system innovation. This research strategy will be most defensible when a national policy aims to encourage specific types of local innovation and previous services research has demonstrated the value of those specific innovations in improving the cost effectiveness of services. Political scientists and organizational sociologists may also discover useful links among "national/state conditions," "national/state system structure," and the "national/state policy process" that generate policy initiatives. Such investigators may also fruitfully examine the comparable processes at the local level that influence local response to outside policy initiatives.

A third strategy is to take a national or state policy initiative, such as a state decision to enter into capitated contracts with local providers or managed care companies, and treat it as a case example in policy research, but to carry out an experimental or quasi-experimental study across local treatment systems of the impact on client access, client outcomes, and other endpoints. The evaluation of state adoption of managed care and capitation contracting in providing publicly funded mental health services in the USA is being evaluated in several states using this type of design.

Thus, the typical outcomes of national and state policy research are changes in local organization or financing of mental health services. It is also important, although more difficult, to determine the effect of national and state policy initiatives on the prevalence and consequences of mental disorder in the general population.

The causal chain of interest includes the effects of national and state conditions, system structure, and policy processes on those characteristics of local service systems thought to be related to their cost-effectiveness. The independent variables of causal interest to national and state policy research bear directly on local service systems as shown by the intersection of Figures 3 and 4 (C1 in Figure 3 and D5, D6, and D7 in Figure 4).

National/state conditions that influence the policy process include such variables as political stability, economic conditions, human resources mix, and cultural conditions such as family and community caretaking traditions. Corresponding factors presumably make up some of the relevant local conditions that influence local policy.

System structure at the national/state level includes such variables as centralization of control and funding, administrative standards, level of funding from sources above the local tax base, eligibility and benefit design, financing incentives for local innovation such as supply-side and demand-side payment incentives. In considering the economic concept of demand-side incentive as affecting local innovation behavior, copayment requirements imposed on persons with psychiatric illnesses and their families, might be included, and also copayment requirements that funding initiatives may impose on the local tax base.

Policy process at all levels includes such variables as leadership, research, and advocacy. Advocacy may come from research and service professionals, from industry, and from consumers and family members. Advocacy can be an important pathway from research findings to policy initiatives.

Mental health system reform in the USA, and specifically the introduction of capitated financing and competitive contracting for the provision of publicly funded mental health care for the severely and persistently mentally ill by many states, is of great interest (Brach, 1995). Several investigators are examining state policy initiatives such as carve-out capitation in mental health Medicaid, interventions related to causal paths D5 to D7 in Figure 4 (e.g., Christianson & Gray, 1994; Christianson & Osher, 1994; Dickey et al., 1996). Christianson, Gray, Kihlstrom, and Speckman (1995a) are studying Utah's prepaid mental health plan and have reported preliminary findings (Christianson et al., 1995b). There is also a study of Colorado's Medicaid carve-out capitated contracting for mental health services (Bloom et al., unpublished). Studies of state Medicaid innovations typically take advantage of a sequential conversion of different regions of a state from fee-for-service reimbursement to capitation contracts to study as a quasi-experiment.

In Colorado the state initially contracted with a for-profit contractor for coverage of a region of the state containing about one-third of the population, contracted with several existing community mental health centers to cover another third of the state's population, and delayed conversion in the rest of the state. Research assessments focus on organizational innovation and adaptation, service utilization, access to services, and individual client outcomes using a pre-post design in each of the three regions. Studies are in progress in several other states. Studies like this of statewide mental health system reform are of necessity relatively large projects, but state mental health authorities, services research investigators, and research funding agencies have joined together to mount major research efforts. By the end of the twentieth century the field will have a set of findings about cost control and outcomes that will set the policy and research agenda for the decade that follows.

As in the other areas of services research, small studies also make important contributions. Cuffel, Wait, and Head (1994) studied a 1990 innovation in the state of Arkansas in which the state transferred hospital funding and admission authority to local mental health agencies, essentially putting state hospitals into a competitive market. The investigators found, as expected, that state hospital use was reduced significantly after decentralization, although the reduction in urban areas was proportionally greater than in rural areas. Contrary to expectation, admissions were not limited to the most severely ill, disruptive, or substance-abusing patients, nor were discharged patients more likely to be readmitted. For patients treated in the state hospitals, communication between the community and the state hospital increased after decentralization.

Studies of national and state innovations such as the examples above make this aspect of mental health services research both feasible and increasingly important in guiding the evolution of mental health care.

3.11.6 CONCLUSION

Mental health services research encompasses a broad range of mental health services research projects. No one project can ordinarily study the whole system of variables at any of the three levels discussed in this Chapter. The scope of mental health services research, however, invites construction of integrated theory, especially in service system and policy domains. Such theory can lay the groundwork for a coordinated approach to empirical research. Furthermore, in spite of its great diversity, mental health services research shares a common objective to understand and improve the effectiveness and efficiency of mental health services for individual consumers and for entire target populations.

3.12.1 INTRODUCTION

A fundamental motivation in science is to understand individual differences. It is *deviation* and *variability* that stimulate scientific curiosity. When do behavioral scientists study constants? One is not compelled to study differences in clinical psychology students who did and did not experience infancy. Instead a comparison of clinical psychology students who do and do not remember parental affect expression in infancy might be compelling. Similarly it is differences among scores on an achievement test that are exciting, not the proportion of psychology graduate students who took the Graduate Record Examination.

Psychological research is conducted to understand *individual differences*. In reporting research results, data are summarized with statistical analyses. In choosing among appropriate statistical procedures, several issues must be considered. First, are the results to be used strictly to describe one sample or will they also be used to draw inferences about the population from which the sample was drawn? *Descriptive statistics* are used for the former purpose, whereas *inferential statistics* are used for the latter. Here several of the more commonly used procedures are discussed. The choice among statistical procedures is also guided by the distribution, the sample size, and of course, the research question. This chapter gives an overview of those statistical procedures. It is not meant to provide a comprehensive explication of each technique, but instead provide a guide to the selection, implementation, and interpretation of appropriate procedures. References which provide comprehensive discussions of the procedures are cited in each section.

Descriptive statistics are used to summarize and describe data from a sample. Measures of *central tendency* and *variability* are fundamental. The former include quantities that represent the typical data from the sample, whereas the latter provide information on the *dispersion* of data within a sample. Data from a *hypothetical* clinical trial comparing the effects of two forms of psychotherapy for depression, interpersonal therapy (IPT) and cognitive-behavioral therapy (CBT), will be used repeatedly in this chapter. Table 1 presents only the data from the CBT group. Taking pedagogical license, the structure of the data will be changed to illustrate a variety of statistical procedures in this chapter. Throughout the chapter X_i will refer to an individual observation of the variable, X. For example, X_{17} represents the X value for subject number 17 (where i is each subject's arbitrarily assigned, unique identifying number, which ranges from 1 to N, in a study of N subjects).

3.12.2 TABULAR AND GRAPHIC DISPLAYS

There are a variety of tabular displays used to summarize data. Hamilton Rating Scale for Depression (HRSD) data will be used for illustration. Initially a *frequency distribution* is constructed by counting the number of occurrences, or frequency, of each value of the variable (X_i). In this case, X_i represents the HRSD rating for subject i, where i ranges from 1 to N. Five columns are included in the frequency distribution that is displayed in Table 2. The first column displays the values of X_i, in ascending order. The second column displays

the frequency for the value of X_i. The third column shows the number of subjects that have a value of X_i or lower, which is referred to as the *cumulative frequency*. In the fourth column the percentage of subjects with each value of X_i, or relative frequency, is displayed. In the fifth column, the cumulative percentage, or *cumulative relative frequency*, is shown, which is the percentage of subjects with a value less than or equal to X_i. Two column totals (sums, which are symbolized Σ) are presented. In the second column, the total of the frequencies is displayed, the value of which should be equal to the sample size (N). The total of the fourth column should equal 100%. Other cell entries worth noting include the final number in the column of cumulative frequencies which should equal N and the final entry in the cumulative relative frequencies column, which should be equal to 100%. Finally, the number of values of X_i provides an initial indication of its variability.

A graphic display of the contents of any of the last four columns can be informative. In these graphs, the x-axis of the graph represents the X_i values and the frequency data are represented on the y-axis. These graphs provide the reader with a sense of the distribution of the data at a glance. For instance, Figure 1 is a bar chart, or *histogram*, displaying the frequencies of each X value. (If there were no variability, only one bar would be displayed.) Figure 2 displays the *relative frequencies*. Figure 3 displays the *cumulative frequency* distribution. Finally, the *cumulative relative frequencies* of the HRSD ratings are displayed in Figure 4. Although Figures 1 and 3 display sample sizes, the proportions presented in Figures 2 and 4 can be readily compared across samples of diverse sizes.

3.12.3 DESCRIPTIVE STATISTICS

Descriptive statistics are summary measures that describe characteristics of data. The two general areas of descriptive statistics that will be discussed here are measures of *central tendency* and measures of variability. The data that were originally shown in Table 1 are now displayed in Table 3, with additional information that will be used for calculations throughout this section.

3.12.3.1 Measures of Central Tendency

The arithmetic mean ($\bar{X}$) of a sample, commonly referred to as the average, is equal to the sum of all observations in the sample, $\sum_{1}^{n} X_i$, divided by the number of observations (N) in the sample.

$$\bar{X} = \frac{\left(\sum_{i=1}^{N} X_i\right)}{N} = \frac{420}{20} = 21$$

The *median*, *Md*, is the middle observation in a sample of ordered data (i.e., ranked from lowest to highest value of X_i). In the case of ordered data, the subscript represents the ascending rank, ranging from 1 to n. With an

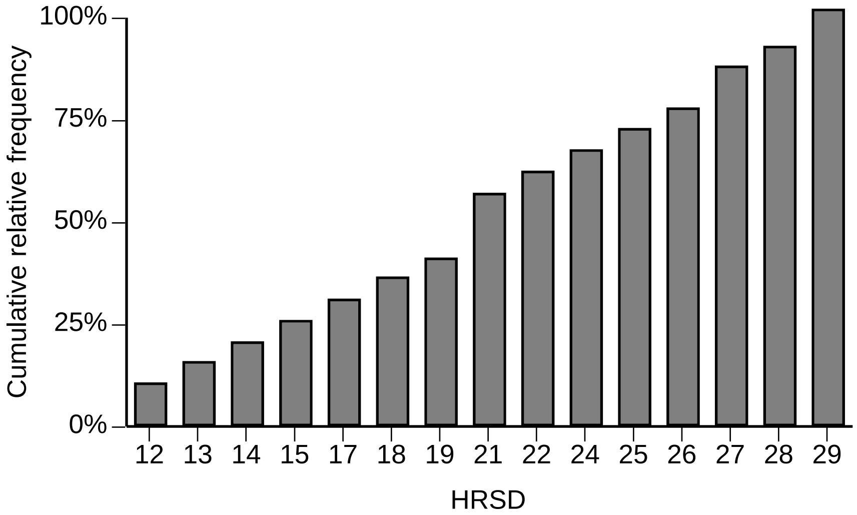

Figure 4 Plot of cumulative relative frequencies of HRSD: CBT group.

even number of observations, the median is the mean of the two middle observations. For instance, there are 20 observations in the sample presented in Table 1. Thus the median of the sample is the mean of the middle two values: 10 and 11:

$$Md = X_{(n+1)/2} = 21 \text{ (mean of 2 middle scores)}$$

The median represents the fiftieth percentile, the point below which half of the data fall. For example, in Table 1, a value of 21 is the median. When the data include a very small number of extreme values, the data set is referred to as skewed (discussed in greater detail below). With *skewed* data, the median is a more representative measure of central tendency than the mean because the mean is influenced by extreme values. For instance, the median is a more appropriate measure of central tendency of the US household income than the mean.

The mode, Mo, is the most frequently occurring value. The modal value can be determined by examining the frequency distribution which is presented in Table 1 and selecting the X_i with the largest value of f_i:

$$\text{Mo} = 21(f = 3)$$

3.12.3.2 Measures of Variability

This chapter began by stating that it is an understanding of individual differences that motivates a great deal of behavioral research. A wide range of statistical procedures are used to analyze differences. Each of the procedures that is discussed in this chapter has to do with differences: individual or group; temporal or conditional. Here the quantities used to assess differences, or *variability*, are discussed. The crudest measure of variability is the *range*, which is the difference between the maximum and minimum value in the data. For instance, in Table 1:

$$\begin{aligned}\text{Range} &= \text{Maximum} - \text{Minimum}\\ &= X_N - X_1 = 29 - 12 = 17\end{aligned}$$

There are several quantities that provide a more comprehensive description of the variability in data. Most are derived from the *Sum of Squares* (*SS*), which is the sum of squared deviations from the mean. The squared deviations are presented in the right-hand column of Table 3. Note that one of the properties of the mean is that the sum of the deviations from the mean is equal to zero:

$$\sum_{i=1}^{N}(X_i - \bar{X}) = 0$$

Notice that the sum of the deviations from the mean in Table 3 is equal to zero. However, the sum of squared deviations from the mean is a useful quantity:

$$SS = \sum_{i=1}^{N}(X_i - \bar{X}) = 640$$

The SS can be used for calculating the *variance* (s^2), which is approximately the mean of the squared deviations from the mean. The variance, a quantity that is commonly used to convey information regarding variability, is calculated as $\frac{SS}{n-1}$, and not $\frac{SS}{n}$, because it provides an unbiased estimator of the population variance. Further discussion of the reasons for this will not be discussed here. Note that, as the sample size increases the difference between $\frac{SS}{n-1}$ and $\frac{SS}{n}$ becomes trivial. The variance is calculated as follows:

$$s^2 = \frac{\sum_{i=1}^{N}(X_i - \bar{X})^2}{N-1} = \frac{640}{20-1} = 33.684$$

Or, if the SS is available:

$$s^2 = \frac{SS}{N-1} = \frac{640}{20-1} = 33.684$$

The *standard deviation* (s), a fundamental measure of variability, is equal to the square root of the variance. It is approximately equal to the average deviation from the mean. It is approximately equal because the deviations have been squared, summed, and divided by $N-1$, not by N, before the square root is computed. Note that by taking the square root, the original unit of measurement is restored.

$$s = \sqrt{s^2} = \sqrt{33.684} = 5.804$$

3.12.3.3 Describing a Frequency Distribution

Modality has to do with the number of modes contained within a frequency distribution. The HRSD data in Figure 1 has one mode and is thus referred to as unimodal. The most commonly occurring value in this sample is 21. There are three observations equal to 21 and there is no other value that is represented as often as 21. Because the y-axis represents the frequency, the mode is the highest point in the plot of the frequency distribution in Figure 1. In contrast to these data, some frequency distributions are bimodal, having two peaks, or multimodal, having more than two peaks.

3.12.3.3.1 Skewness

If one folds the distribution, vertically in the middle and one half can be superimposed on the other, the distribution is *symmetric*. The extent to which a frequency distribution diverges from symmetry is described as *skewness*. With help from Bill Gates and a few of his peers, incomes in the United States are positively skewed. The skewness, which is one aspect of the departure from symmetry, is described as either skewed to the right, positively skewed as shown in Figure 5, or skewed to the left, negatively skewed, as shown in Figure 6. For example, with a different set of HRSD data, a positively skewed distribution is one in which there are a very few severely depressed scores, whereas a distribution in which there are a very few number of euphoric scores might be negatively skewed.

3.12.3.3.2 Kurtosis

Kurtosis has to do with the extent to which a frequency distribution is peaked or flat. A normal bell-shaped distribution is referred to as a *mesokurtic* shape distribution. An example of this, a nicely rounded distribution, is shown in Figure 7. Many human traits are normally distributed including height and intelligence. A *platykurtic*, like a platypus, is a somewhat flat creature. For instance, as shown in Figure 8, this would describe data in which there are several modes, which cluster around, and include, the median. A *leptokurtic* distribution is more peaked. In Figure 9 hypothetical data show that such data would be characterized by a very high, unimodal peak, at the median.

3.12.3.4 Other Graphic Displays

Two other formats for graphic display are the *Stem and Leaf* and the *Box and Whisker* plots. These graphic displays, which are described in detail by Tukey (1977), each provide the researcher with a great deal of information about the distribution of the data. The importance of examining such plots cannot be overemphasized. One outlier (i.e., extreme score) in a data set can markedly alter the mean and exaggerate trivial group differences. The existence of outliers is most readily apparent in a good graph.

A *Stem and Leaf plot* is an efficient method of displaying a frequency distribution. In Figure 10, the vertical line, called the stem, displays the possible values, ranging from the minimum (at the top) to maximum value (at the bottom). Each leaf represents an individual with a particular value. A leaf could be an "x," an asterisk, or more commonly the value itself. A data value (on the stem) with several leaves is a frequently occurring value. Of course, the mode has the most leaves.

Box and Whisker plots are based on five points as shown in Figure 11. The first three of those have been discussed: the median, the minimum, and maximum. The final two points of the box and whisker plot are the values that fall midway between each extreme score and the median. These are the first and third *quartiles*. A long thin box is drawn with the latter two points serving as the *hinges*. A horizontal bar is drawn through the median. *Whiskers* are drawn at the two extreme values. The figure illustrates how easily outliers are detected in a Box and Whisker plot. In some situations, the plot is more informative when an identifier is used to label values such as an outlier.

When an outlier is identified, the researcher must determine if the value is real or if it is a keypunch error. The raw data forms will help

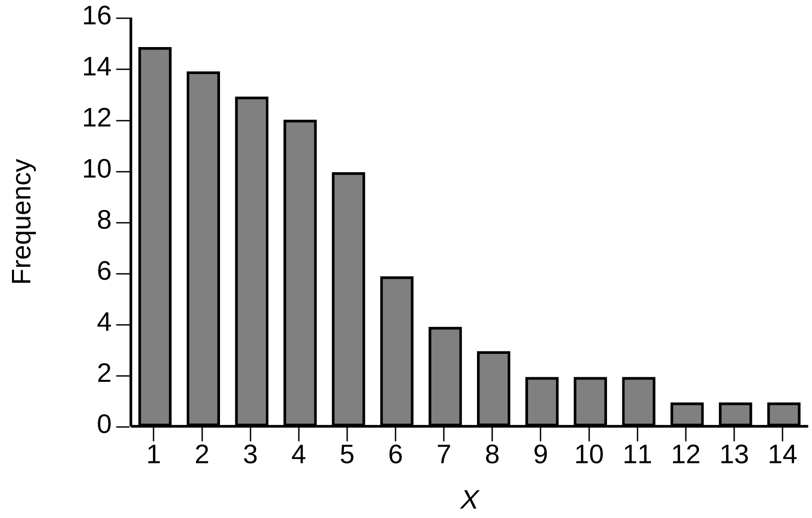

Figure 5 Example of positively skewed data.

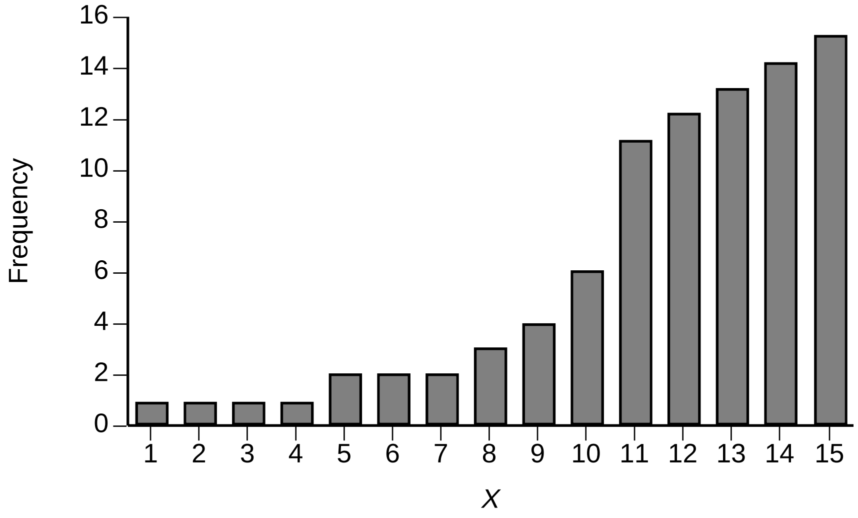

Figure 6 Example of negatively skewed data.

one correct keypunch errors. However, extreme scores are not necessarily incorrect values. In a study of depression, an HRSD score of 58 is possible, but extremely rare. In analyzing data in which valid extreme values have been identified, one has several strategies to choose from. First, a nonparametric procedure could be used in which the ranks of the raw data values are used. In such a case the minimum and maximum are equal to 1 and N, respectively. Second, a transformation of the data values using either the natural logarithm, where $y' = \ln(y)$, or square root of the original scale $y'' = \sqrt{y}$. Third, an extreme score might be *winsorized*, a process in which an outlier is simply recoded to the second highest value (see Tukey, 1977). Alternative strategies for outliers are discussed in detail by Wilcox (1996).

3.12.3.5 Statistical Software

Many of the statistical procedures that are described in this chapter involve tedious calculations. This leaves a great deal of room for computational errors. For all practical purposes, most statistical analyses in psychological research are conducted using a computer. There is a wide variety of statistical software that is commercially available for personal computers. Software that is commonly used in the social sciences includes SPSS, SAS, BMDP, and SYSTAT. Comprehensive reviews of statistical software are available (Lurie, 1995; Morgan, 1998). The choice among statistical software has to do with the statistical procedures that are included, the data management capabilities, and the ease of use. Nevertheless, a

statistical procedure should only be used in appropriate situations. A thorough understanding of the statistical technique, the assumptions, and a familiarity with the estimation procedure is necessary. Furthermore, the user must have the background necessary to interpret the results that are generated by the software. One of the goals of this chapter is to provide the reader with such a background for a variety of descriptive and inferential procedures. In addition, the appendix of this chapter includes SPSS command lines for each of the analyses that is discussed (SPSS, 1997). SPSS is used for illustration here because it is accessible with minimal programming skills, it covers a wide array of statistical procedures, and it has excellent data management capacity.

3.12.4 INFERENTIAL STATISTICS

Once again, an *inferential* statistical test is used to make an inference about a population based on data from a sample. In choosing among inferential procedures, one must consider the nature of both the independent and dependent variable, whether a between-subject design or within-subject design is employed, and the sample size. The procedures that are presented below are organized to reflect such considerations. Initially statistical procedures for between-subject designs are discussed. This is followed by a discussion of procedures for within-subject designs. In each of those sections both parametric and nonparametric procedures are considered. The distinction between parametric and nonparametric procedures is discussed in detail in Section 3.12.4.2.

First a digression into general features regarding inferential tests. A statistical test is used to draw an inference about a population(s) based on sample data. The test is used to examine the research question at hand. For instance, "Which of two forms of psychotherapy is more effective for the treatment of depression?" For purposes of hypothesis testing, the question is reframed into a null hypothesis (i.e., a hypothesis of *no difference*). For example, "There is no difference in the effects of CBT and IPT for the treatment of depression." In conducting such tests, the researcher might make a correct decision, but errors are certainly possible. Consider the correspondence between the *truth* and the research results (see Table 4). Assume that with omniscient (noninferential) ability, someone is able to describe the *truth* (e.g., population characteristics) without conducting a statistical test. Thus the omniscience. (Every department has at least one member with self-rated ability of that level.) For example, consider a clinical trial in which the post-treatment psychopathology of two groups (CBT and IPT) is being compared. Our colleague, Dr. Omniscient, could tell us whether or not the severity of psychopathology in the two groups differs. If there is no difference in the population, the correct decision would be to conclude that there is no difference (i.e., fail to reject the null hypothesis). In contrast, if there is no population difference, yet we find a difference, we would be in error. Specifically, rejecting a true null hypothesis is referred to as *Type I Error*. The probability of Type I Error is referred to as the alpha level (α).

On the other hand, if Dr. Omniscient tells us that there is, in fact, a treatment difference (i.e., population treatment differences), we would be correct if we detected the difference (rejected a false null hypothesis). The probability of such a rejection is referred to as *statistical power*. In contrast, we would be in error if we fail to detect the treatment difference (i.e., fail to reject a false null hypothesis). This is referred to as *Type II Error* and the $p(\text{Type II error}) = \beta$. In the absence of Dr. Omniscient's assistance, replication of results in subsequent studies provides convincing evidence that our inference was likely to be accurate.

One further general digression regarding inferential statistics. In general a test statistic

Table 4 Cross-classigication of the "truth" and research results.

Results of research	*Placebo = Active* (H_0 true)	*Placebo ≠ Active* (H_0 false)
No difference (CBT = IPT)	Correct decision	Type II error
Difference (CBT = IPT)	Type I error	Correct decision "Power"

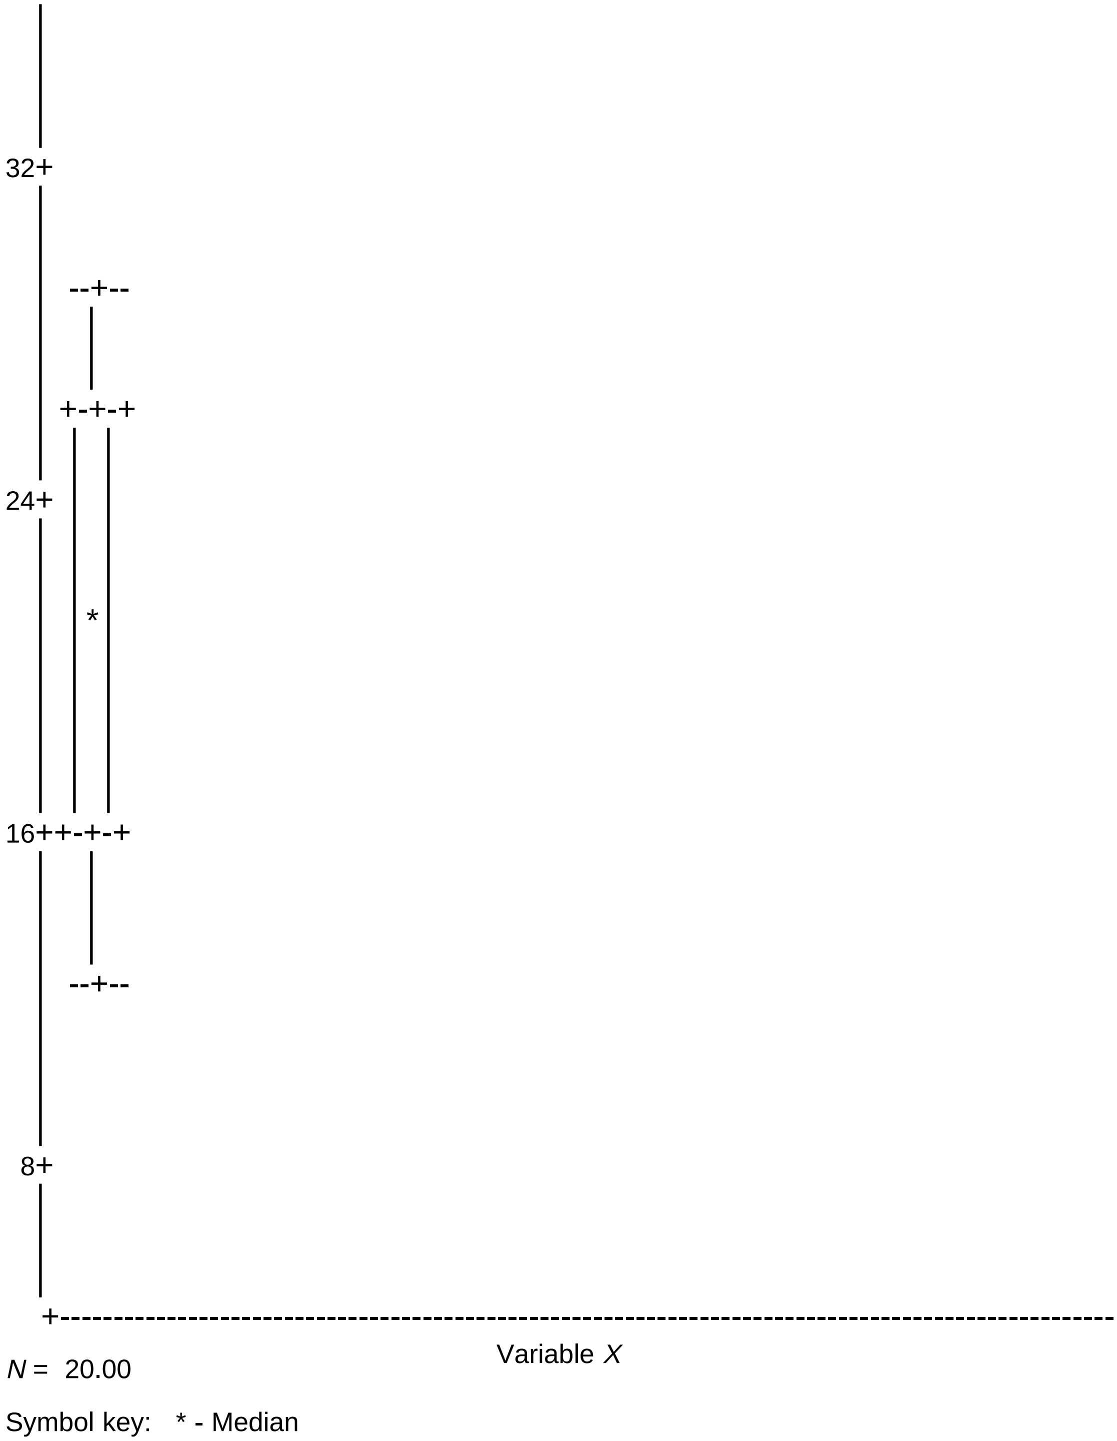

Figure 11 HRSD: Box and Whisker Plot.

is a ratio of a statistic (e.g., difference in means) to its *standard error*. Loosely speaking, the standard error is an estimate of the variability of the statistic in the population. Stated differently, and hypothetically, if the experiment were conducted repeatedly, say 10 000 times (with the same sample size each time), and the quantity of interest (e.g., difference between two means) were calculated in each of those experiments, the standard error would represent the standard deviation of that distribution (the sampling distribution) of that quantity (e.g., the standard deviation of the differences between two means).

As stated earlier, one component of each inferential statistical test is the null hypothesis,

Table 5 Hamilton Depression Ratings (X_i) for 20 patients (IPT group).

$$\text{SS} = \sum (X_i - \bar{X})^2 = 414.95$$

$$s^2 = \frac{\text{SS}}{n-1} = \frac{414.95}{20-1} = 21.839$$

$$s = \sqrt{s^2} = \sqrt{21.839} = 4.673$$

H_0. In fact that is one of the eight components of the hypothesis testing procedure which are listed below:

(i) State research question.

(ii) State two hypotheses which are mutually exclusive and exhaustive:

 (a) null hypothesis (e.g., $H_0 : \mu_1 = \mu_2$)

 (b) alternative hypothesis (e.g., $H_A : \mu_1 \neq \mu_2$).

(iii) Choose an appropriate statistical test

(iv) Specify the critical value for the statistical test and the alpha level (both of which are discussed below).

(v) Collect data.

(vi) Perform calculations.

(vii) Make decision regarding H_0.

(viii) Conclusion. The results are interpreted as an inference about the population (which the sample represents) based on the sample data. The *generalizability* of the findings should be discussed. Inferences about the results cannot be generalized beyond the scope of the data that was examined. For instance, results from a clinical trial for the treatment of patients with depression cannot be used to draw inferences about the treatment of patients with panic disorder.

3.12.4.1 One- vs. Two-tailed Tests

In some settings, the researcher might have preconceived expectations regarding the outcome of the experiment. For instance, it might be expected that a novel treatment is superior to the standard. The researcher can then choose to specify the null hypothesis as that of *no treatment difference* or *superiority of the novel treatment*. A two-tailed null hypothesis is designed to detect any difference, positive or negative, whereas a one-tailed null hypothesis is designed to detect a difference in the prespecified direction (e.g., efficacy) but it would fail to detect the opposite (e.g., detrimental) effects. It is often as important, and ethically compelling, to detect detrimental treatments as it is to detect efficacious treatments. A two-tailed test is used for a nondirectional null hypothesis and a one-tailed test is used for a directional null hypothesis. Although there is debate regarding the exclusive use of two-tailed tests, there is a consensus that the rationale for a one-tailed test must be stated *a priori*. That is, if a one-tailed test is to be used, it must be so stated prior to study implementation and data collection. There has been an extensive discussion in the literature of the costs and benefits of one and two-tailed tests (e.g., Fleiss, 1981, pp. 27–29; Hopkins, Glass, & Hopkins, 1987, pp. 164–165, 205–206). All examples in this chapter employ two-tailed, nondirectional tests.

3.12.4.2 Parametric vs. Nonparametric Tests

Technically speaking, one must not use parametric tests such as a *t*-test and an ANOVA unless assumptions such as normality are fulfilled. By normality, it is assumed that the sample come from a population with normally distributed data. Briefly, in a normal distribution, which is bell-shaped, the mean, median, and mode are equal. The distribution is symmetrical around these measures of central tendency. The shape of a normal distribution is determined by the population means and variance. The nonparametric alternatives to the *t*-test and the ANOVA are the Mann–Whitney test and Kruskal–Wallis test. Neither of these makes the normality assumptions. Many of the nonparametric procedures require a simple rank transformation of the data (Conover, 1980; Sprent, 1989). This involves pooling the data from all subjects, regardless of treatment group, and ranking in ascending order based on the value of the dependent variable. The subject with the lowest value is assigned the rank of 1. The subject with the next lowest is assigned the value of 2, and so on, until the subject with the highest value is assigned a rank of N. If all assumptions have been reasonably fulfilled and all other aspects of the analysis are equal, parametric tests generally have more statistical power than nonparametric tests. However, if the assumptions are not met, parametric tests could provide misleading results about the population which the sample represents.

3.12.4.3 Between-subject Designs: Dimensional and Ordinal Dependent Variables

3.12.4.3.1 t*-test*

The t-test is used to compare the means of two groups. For instance, in a clinical trial, the severity of depression of two treatment groups (IPT and CBT) can be compared with a t-test. The HRSD is the dependent variable. The *null hypothesis* is that the population means do not differ: $H_0 : \mu_1 = \mu_2$ and the alternative hypothesis is that population means are not the same: $H_A : \mu_1 \neq \mu_2$.

The test is simply a ratio of the *between-group* differences relative to the *within-group* differences. It is used to ask the question, "Is the mean difference *between groups* large relative to the fluctuation that is observed *within* each group?" To illustrate this, the data from the CBT group (presented in Table 3) are compared with data from the other group of subjects in the hypothetical clinical trial that was described earlier, those assigned to IPT (see Table 5).

The algorithm for the t-test is a ratio of *between-group* variability to *within-group* variability:

$$t = \frac{\bar{X}_1 - \bar{X}_2}{S_{\bar{X}_1 - \bar{X}_2}}$$

where the numerator represents the between-group variability (i.e., difference between the group means) and the denominator is derived from the pooled variance. The pooled variance is estimated as:

$$s_p^2 = \frac{(SS_1 + SS_2)}{(n_1 - 1) + (n_2 - 1)}$$

and

$$s_{(\bar{X}_1 - \bar{X}_2)} = \sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}}$$

Applied to the CBT vs. IPT data set: the pooled variance estimate,

$$s_p^2 = \frac{(SS_1 + SS_2)}{(n_1 - 1) + (n_2 - 1)}$$

$$= \frac{640.0 + 414.95}{(20 - 1) + (20 - 1)} = 27.76$$

and

$$s_{(\bar{X}_1 - \bar{X}_2)} = \sqrt{\frac{s_p^2}{n_1} + \frac{s_p^2}{n_2}} = \sqrt{\frac{27.76}{20} + \frac{27.76}{20}} = 1.67$$

$$t = \frac{\bar{X}_1 - \bar{X}_2}{s_{(\bar{X}_1 - \bar{X}_2)}} = \frac{21.00 - 15.05}{1.67} = 3.56$$

This t-statistic is compared with a critical value from tabled values, which can be found in the appendix of any statistics book. To identify that critical value, one must determine the *degrees of freedom* (*df*). Although a discussion of the meaning of degrees of freedom is beyond the scope of this chapter, a value for *df* is often needed to find the critical value of a test statistic. In the case of a two-group t-test, *df* is equal to the total number of subjects minus the number of groups:

$$df = n_1 + n_2 = 20 + 20 - 2 = 38$$

Using this value for *df*, and a two-tailed alpha level of 0.05, the *critical* t-statistic is 2.024. The *observed* t of 3.56 exceeds this critical value. Thus the null hypothesis is rejected and one can conclude that the population means are not identical. IPT treatment is superior to CBT. Without the t-test it was apparent that the IPT mean indicated lower symptom severity as measured by the HRSD than the CBT mean. To get a handle on the magnitude of that difference, it is compared with the within-group standard deviations. The IPT mean was over 6 HRSD points lower, which exceeds one within-group standard deviation (i.e., $s_{\text{IPT}} = 4.67$ and $s_{\text{CBT}} = 5.80$). Using the t-test, one can conclude that the difference in group means is greater than would be expected by chance.

The *assumptions* of the t-test include:

(i) Independence among observations. For example, one subject cannot re-enroll in the clinical trial to try another treatment if the initial treatment does not result in symptom remission. If that were permitted, some subjects would contribute multiple observations to the sample and those observations would not be independent.

(ii) The data are normally distributed in the population. Technically, this assumption has to do with the distribution of the *difference in means*, $\bar{X}_1 - \bar{X}_2$ or the population sampling distribution of $\mu_1 - \mu_2$. This assumption is generally met if the sample distributions of the raw data (i.e., the actual measurements), as opposed to the mean differences, are normal, or if the sample sizes are *reasonably* large.

(iii) Homogeneity of variance. The population variances are presumed to be equal. There are several tests of homogeneity of variance including Levene's (1960) test of equality of variances, Bartlett's test for homogeneity of variances, or Hartley's F-Max test (1950). These tests will not be discussed here. In calculating the t-test statistic, one generally uses a pooled variance estimate. However, when the assumption cannot be met, separate variance estimates can be incorporated into the t-test, or another procedure altogether, such as the Mann–Whitney test (discussed below), can be used. In the case of *heteroscedasticity* (unequal group variances), a different algorithm for the t-test is used which incorporates separate variance estimates in the denominator. In addition, an adjustment in degrees of freedom is necessary. This will not be discussed here, but is presented in a variety of other references (Armitage & Berry, 1987; Fleiss, 1986; Zar, 1996).

In summary, the hypothesis testing steps for the t-test are as follows:

(i) State research question. Do CBT and IPT have similar effects for the treatment of patients with depression?

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) $H_0: \mu_1 = \mu_2$

(b) $H_A: \mu_1 \neq \mu_2$

(iii) If the assumptions appear to be fulfilled, choose the t-test to evaluate the hypotheses.

(iv) The critical value for the t-test with $\alpha = 0.05$ and $df = 38$ is 2.024. If $|t_{\text{observed}}| > t_{\text{crititcal}}$, reject H_0.

(v) Data are displayed in Table 3 for the CBT group and Table 5 for the IPT group.

(vi) Calculations were described above.

(vii) Decision regarding H_0 Because $|t_{\text{observed}}| > t_{\text{crititcal}}$ (i.e., $3.56 > 2.024$), reject H_0.

(viii) Conclusion. IPT is a more effective treatment of depressive symptoms in these patients with major depressive disorder.

3.12.4.3.2 Mann–Whitney test

If the assumptions of the t-test cannot be met, yet the observations are independent, the Mann–Whitney test, (also called the Wilcoxon test), may be an appropriate method for two group comparisons, if the data are at least ordinal in nature. An ordinal measurement need not have equal intervals between units, but must be ordered numbers (e.g., 1st, 2nd, 3rd, . . .). The Mann–Whitney test can be used to compare two groups without making any distributional assumptions. It is used when there is reason to believe that the data are not normally distributed, when the sample sizes are small, or when the variances are heterogeneous. It can be used for dimensional data (e.g., HRSD), as well as ordered categorical data [e.g., illness severity categories rated on a Likert scale from 0 (none) to 10 (severe)].

Analyses are not conducted on the raw data, but instead on rank transformed data, as described above. For instance, using the data from the clinical trial comparing IPT and CBT, the ranked data are displayed in Table 6. Instead of analyzing the actual Hamilton scores (the dependent variable), each of the scores is ranked, with the lowest rank assigned a rank of 1 and the highest assigned a rank of N. For purposes of ranking the data are pooled across groups. In the case of ties, the midpoint is used. Subsequent calculations are conducted with the ranks.

The rationale behind the Mann–Whitney test is that if the treatments are equally effective, one would expect about half of each group to be below the median rank for the pooled sample. Another way to think of it is to consider all possible pairs of data across groups: subject 1 from group 1 with subject 1 from group 2; then subject 1 with subject 2 from group 2; . . . subject 20 from group 1 with subject 20 from group 2.

Table 6 Hamilton Rating Scale of Depression for patients in the IPT group ($N = 20$) and patients in the CBT group ($N = 20$): raw ratings (X_i) and rank-transformed ratings ($R(X_i)$).

	IPT		*CBT*	
	X_{i1}	$R(X_{i1})$	X_{i2}	$R(X_{i2})$
	12	7	13	10.5
	12	7	12	7
	17	15	14	12
	18	18	15	13
	19	24	17	15
	19	24	18	18
	19	24	21	30
	19	24	21	30
	19	24	21	30
	12	7	22	32
	13	10.5	12	7
	17	15	25	34
	18	18	24	33
	19	24	19	24
	19	24	28	38
	19	24	27	36.5
	6	1	26	35
	7	2	29	39.5
	8	3	29	39.5
	9	4	27	36.5
Total	301	299.5	420	520.5

Examine whether or not in more than half of the ranked pairs the group 1 member is lower than its counterpart from group 2. That is, we would count the number of times that a subject in group 1 has a higher rank than a subject in group 2. Computationally, the tedious process of all $n_1 \cdot n_2$ comparisons need not be made.

The computations for the Mann–Whitney U test that are now described are based on the formula for the case where both n_is are less than or equal to 20. The total number of subjects across groups is $N = n_1 + n_2$ and $U = n_1 \cdot n_2 + \frac{n_1(n_1+1)}{2} - R_1$, where R_1 is the sum of the ranks for group 1. Note that, in general, the sum of N ranks $= \frac{N(N+1)}{2}$. More specifically, in this case, $\frac{40(40+1)}{2} = 820$, which is equal to the sum of the ranks: $299.5 + 520.5 = 820$.

The observed U statistic (U_{obs}) is compared with a critical range which is tabled in most introductory statistics texts (see for example, Fleiss, 1986; Zar, 1996). The critical range is a function of the sample size of each group.

$$U_{obs} = n_1 \cdot n_2 + \frac{n_1(n_1+1)}{2} - R_1$$

$$= 20 \cdot 20 + \frac{20 \cdot 21}{2} - 299.5 = 310.5$$

For the Mann–Whitney test, the hypothesis testing steps are as follows:

(i) State research question. Do CBT and IPT have similar effects for the treatment of patients with depression?

(ii) State two mutually exclusive and exhaustive hypotheses with respect to the population medians (M_k).

$H_0: M_1 = M_2$

$H_A: M_1 \neq M_2$

(iii) Choose the Mann–Whitney test to evaluate the hypotheses.

(iv) The critical values for the Mann–Whitney test, with $\alpha = 0.05$ and $n_1 = n_2 = 20$, are 127 and 273. Thus, if $U_{\text{obs}} \leqslant 127$ or $U_{\text{obs}} \geqslant 273$, reject H_0.

(v) The ranked data are displayed in Table 6 for the IPT and CBT groups.

(vi) Calculations were described above.

(vii) Make decision regarding H_0.

$U_{\text{obs}} \geqslant U_{\text{critical}}$ (i.e., $310.5 \geqslant 273$), thus reject H_0.

(viii) Conclusion: IPT is a more effective treatment of depressive symptoms in patients with major depressive disorder.

The assumptions of the Mann–Whitney test include:

(i) The two samples have been independently and randomly sampled from their respective populations.

(ii) The groups are independent.

(iii) The scale of measurement is at least ordinal.

For larger samples (i.e., when n_1 or n_2 is greater than 20), a Normal Approximation can be used for the Mann–Whitney test (see Conover, 1980).

3.12.4.3.3 One-way analysis of variance

When more than two groups are compared on a dimensional dependent variable, a fixed effects analysis of variance (ANOVA) is used. As with the *t*-test, the test statistic is a ratio of between-group differences to within-group differences. In this case the sum of squares is the quantity representing variability. The sums of squares was introduced earlier as the sum of squared deviations from the mean. For example, consider the clinical trial that has been described above, with the addition of a placebo group. Say that patients are randomly assigned to one of *three* treatments: CBT, IPT, or a psychotherapy placebo. The psychotherapy placebo patients see their clinicians for medical management (MM)—a brief nondirective/reflective talk therapy. The data from the MM group are presented in Table 7. The efficacy of the three treatments for depression in this study can be compared using an ANOVA, once again with the HRSD as the dependent variable.

Initially, three different types of sums of squared deviations are computed. The total sum of squared deviations (SS_{Total}), sum of squared deviations accounted for by treatment group ($\text{SS}_{\text{Treatment}}$), and the residual sum of squared deviations, also referred to as "sum of squares error" ($\text{SS}_{\text{Residual}}$), are calculated as described below. There are several aspects about these three quantities that are worth noting at this point. First, the SS_{Total} is the sum of squared deviations from the grand mean (i.e., for all subjects pooled, without regard to treatment group). Second, $\text{SS}_{\text{Treatment}}$ is a measure of the squared deviations of the treatment group means from the grand mean. It can be thought of as the sum of squares that is *explained* (by knowing what treatment the subjects received). Third, the sum of squared differences between each observation and its sample mean is the $\text{SS}_{\text{Residual}}$. It represents the sum of squares that is not explained by treatment, and in this context, is the difference between SS_{Total} and $\text{SS}_{\text{Treatment}}$. These quantities are used in the *F*-test of the fixed effects ANOVA that is presented in Table 8 (the calculation of each quantity is also described in Table 8).

The assumptions of fixed effects ANOVA are:

(i) The samples are independent.

(ii) The populations from which the sample are drawn are normally distributed.

(iii) Each of the populations has the same variance.

For a fixed effects ANOVA, the hypothesis testing steps are as follows:

(i) State research question. Do CBT, IPT and MM have similar effects for the treatment of patients with depression?

(ii) State two mutually exclusive and exhaustive hypotheses:

$H_0 : \mu_1 = \mu_2 = \mu_3$

$H_{A_1} : \mu_1 \neq \mu_2$ or $H_{A_2} : \mu_1 \neq \mu_3$ or $H_{A_3} : \mu_2 \neq \mu_3$

(iii) If assumptions are met, choose the fixed effects ANOVA to evaluate the hypotheses.

(iv) The critical value for the *F*-test with $\alpha = 0.05$ and $df = 2{,}57$ is 3.16 (*df* is defined in Table 8). If $F_{\text{observed}} > F_{\text{critical}}$, reject H_0.

(v) Data are displayed in Tables 3, 5, and 7 for the CBT, IPT, and MM groups, respectively.

(vi) Calculations are described above in text and in Table 8.

(vii) Make decision regarding H_0. Since $F_{\text{observed}} > F_{\text{critical}}$ (i.e., 10.966 > 3.16) reject H_0.

(viii) Conclusion: There is a significant difference in severity of depression among the treatments. And which is superior?

Table 7 Hamilton Depression Ratings (X_i) for 20 patients in the MM group.

	X_i	X_i^2	$X_i - \bar{X}$	$(X_i - \bar{X})^2$
	16	256	−6.25	39.0625
	16	256	−6.25	39.0625
	17	289	−5.25	27.5625
	17	289	−5.25	27.5625
	19	361	−3.25	10.5625
	19	361	−3.25	10.5625
	19	361	−3.25	10.5625
	19	361	−3.25	10.5625
	20	400	−2.25	5.0625
	20	400	−2.25	5.0625
	21	441	−1.25	1.5625
	21	441	−1.25	1.5625
	22	484	−0.25	0.0625
	25	625	2.75	7.5625
	27	729	4.75	22.5625
	28	784	5.75	33.0625
	28	784	5.75	33.0625
	29	841	6.75	45.5625
	31	961	8.75	76.5625
	31	961	8.75	76.5625
Total	445	10385	0	483.75

$$\bar{X} = \frac{\sum_{1}^{n} X_i}{n} = \frac{445}{20} = 22.25$$

$$\text{SS} = \sum (X_i - \bar{X})^2 = 483.75$$

$$s^2 = \frac{\text{SS}}{n-1} = \frac{483.75}{20-1} = 25.46$$

$$s = \sqrt{s^2} = \sqrt{25.46} = 5.046$$

3.12.4.3.4 ANOVA: Post hoc *tests*

A significant omnibus *F*-test indicates that the null hypothesis is rejected: $H_0 : \mu_1 = \mu_2 = \mu_3$. Nonetheless, further analyses are necessary to determine where the difference lies, that is, which groups are significantly different from each other. A variety of *post hoc* tests can be used for this purpose. A *post hoc* test is designed to be used *only* after an omnibus *F*-test is statistically significant. Each test incorporates the mean square within (*MSW*), which comes from the calculations that are presented in the ANOVA table (Table 8). The *MSW* is the denominator of the *F*-test. A nonsignificant omnibus *F*-test, however, indicates that there is not a difference in means among the groups. Of course, when there is no difference, there is no need to look for differences. Consequently, the use of a *post hoc* test after a nonsignificant omnibus *F*-test is inappropriate.

Post hoc procedures provide a strategy for multiple comparisons while at the same time maintaining the probability of Type I error (i.e., the probability of detecting differences that do not actually exist). This is in stark contrast with the inappropriate strategy of following a significant omnibus *F*-test with several *t*-tests, each used to compare a pair of groups. That approach fails to account for the multiple tests, and as a consequence, increases the probability of Type I error. Three *Post hoc* tests are described below. The choice among these tests is based on the research question and the design of the study.

(i) Tukey's Honestly Significant Difference

Tukey's Honestly Significant Difference (HSD) test is used to compare all *pairs* of groups means. HSD can be applied when each of the pairwise comparisons is of interest to the researcher, or when the researcher does not have specific hypotheses about which group means will differ. Initially the groups means are calculated. In the hypothetical clinical trial example that has been discussed in this chapter, the groups are arranged in ascending order of their means: IPT ($\bar{X} = 15.05$), CBT ($\bar{X} = 21.00$), MM ($\bar{X} = 22.25$). Note that with k groups there are $\frac{k(k-1)}{2}$ pairwise comparisons. Thus, in this example, there are $\frac{k(k-1)}{2} = \frac{3(3-1)}{2} = 3$ comparisons: IPT vs. CBT, IPT vs. MM, and CBT vs. MM.

Table 8 ANOVA Table

Source	*SS*	*df*	*MS*	*F*
Treatment	592.033	2	296.017	10.966
Within	1538.697	57	26.995	
Total	2130.730	59		

$$
\begin{aligned}
\mathrm{SS}_{\mathrm{Total}} &= \sum_{i=1}^{n}(X_i - \bar{X}_{..})^2\\
&= (12 - 19.43)_2 + (12 - 19.43)^2\\
&\quad + \cdots + (31 - 19.43)^2(31 - 19.43)^2\\
&= 2130.733\\
\mathrm{SS}_{\mathrm{Treatment}} &= \sum_{j=1}^{p} n_j(X_j - \bar{X}_{..})^2\\
&= 20(21.00 - 19.43)^2\\
&\quad + 20(15.05 - 19.43)^2\\
&\quad + 20(22.25 - 19.43^2 = 592.033)\\
\mathrm{SS}_{\mathrm{Within}} &= \sum_{i=1}^{N}(\bar{X}_{ij} - \bar{X}_j)^2\\
&= (12 - 21)^2 + (12 - 21)^2\\
&\quad + \cdots + (31 - 21)^2\\
&\quad + (31 - 21)^2 = 1538.697\\
\mathrm{df}_{\mathrm{Treatment}} &= k - 1, \text{where } k = \text{number of groups}\\
\mathrm{df}_{\mathrm{Within}} &= N - k\\
\mathrm{df}_{\mathrm{Total}} &= N - 1\\
\mathrm{MS}_{\mathrm{Treatment}} &= \frac{\mathrm{SS}_{\mathrm{Treatment}}}{\mathrm{df}_{\mathrm{Treatment}}}\\
\mathrm{MS}_{\mathrm{Within}} &= \frac{\mathrm{SS}_{\mathrm{Within}}}{\mathrm{df}_{\mathrm{Within}}}\\
F &= \frac{\mathrm{MS}_{\mathrm{Treatment}}}{\mathrm{MS}_{\mathrm{Within}}}
\end{aligned}
$$

The three pairwise mean differences are then calculated. The HSD test statistic, q, a ratio of the mean difference over the standard error, is computed for each pairwise comparison. For each comparison, if the observed $q >$ critical q (a tabled value), the null hypothesis of no difference between the pair of means is rejected. When there are an equal number of subjects per group, the standard error (*se*) is calculated as:

$$se = \frac{\sqrt{MSE}}{n_k} = \frac{\sqrt{26.995}}{20} = 1.16$$

where MSE comes from the ANOVA table (Table 8) and n_k is the number of subjects per group. The algorithm for unequal sample sizes can be found in other texts (e.g., Zar, 1996). The results are presented in Table 9.

The hypothesis testing steps for Tukey's HSD are as follows:

(i) State research question. The ANOVA results indicated that the IPT, CBT, and MM do not have similar effects for the treatment of patients with depression. Which pairs of groups differ?

(ii) State two mutually exclusive and exhaustive hypotheses for each pairwise comparison:

(a) $H_0: \mu_{\mathrm{IPT}} = \mu_{\mathrm{CBT}}$
$H_A: \mu_{\mathrm{IPT}} \neq \mu_{\mathrm{CBT}}$
(b) $H_0: \mu_{\mathrm{IPT}} = \mu_{\mathrm{MM}}$
$H_A: \mu_{\mathrm{IPT}} \neq \mu_{\mathrm{MM}}$
(c) $H_0: \mu_{\mathrm{CBT}} = \mu_{\mathrm{MM}}$
$H_A: \mu_{\mathrm{CBT}} \neq \mu_{\mathrm{MM}}$

(iii) Choose Tukey's HSD as a *post hoc* test to evaluate the hypotheses.

(iv) The critical value for the q-test with $\alpha = 0.05$ and df = 3,56 is 3.408. (Note that $df = k, v$, where $k =$ number of groups and $v = n - k - 1$.) Reject H_0 if $q > 3.408$.

(v) Data are displayed in Table 9 for the three pairwise comparisons.

(vi) Calculations were described above.

(vii) Decisions regarding H_0.

IPT vs. CBT: $q_{\mathrm{observed}} > q_{\mathrm{critical}}$
(i.e., 5.13 > 3.408), thus reject H_0.
IPT vs. MM: $q_{\mathrm{observed}} > q_{\mathrm{critical}}$
(i.e., 6.21 > 3.408), thus reject H_0.
CBT vs. MM: $q_{\mathrm{observed}} < q_{\mathrm{critical}}$
(i.e., 1.07 < 3.408), thus do not reject H_0.

(viii) Conclusion: IPT was more effective than either CBT or MM for the treatment of depressive symptoms in patients with major depressive disorder. There was no difference between CBT and MM for the treatment of depressive symptoms.

(ii) The Dunnett test

The Dunnett test is to be used when a control group is to be compared with each of several other treatments, and when no other comparisons are of interest. For instance, it could be used to demonstrate the efficacy of each treatment relative to placebo, but not to examine differences between active treatments. In the example that has been discussed, the

Table 9 Tukey HSD pairwise comparisons

Comparison	*Mean difference*	*se*	*q*
IPT vs. CBT	5.95	1.16	5.13
IPT vs. MM	7.20	1.16	6.21
CBT vs. MM	1.20	1.16	1.07

Dunnett test could be used for two comparisons: (i) CBT vs. MM, and (ii) IPT vs. MM. It could be used to show that IPT and CBT each have *active ingredients*; but the Dunnett test could not be used by members of the IPT and CBT camps to settle the score of whose method is superior. The Dunnett test, which will not be illustrated here, is described in detail in Fleiss (1986).

(iii) Scheffe Post Hoc *Procedure*

The Scheffe test is a more general procedure than those described above. It is not restricted to pairwise comparisons, but can evaluate comparisons of any linear combination of means. For instance, in the above example, one might have two comparisons of interest: (i) active (CBT and IPT) vs. placebo (MM), and (ii) CBT vs. IPT. The Scheffe procedure would be appropriate for those comparisons. The Scheffe test is somewhat more conservative than others in that it has less statistical power. For that reason some criticize the test for being more likely to miss true differences. Others consider the conservative nature of the test appealing. The Scheffe test will not be applied here. It is discussed in detail in Fleiss (1986).

3.12.4.3.5 Kruskal–Wallis test

The Kruskal–Wallis test (1952) is a nonparametric approach to the one-way ANOVA. The procedure is used to compare three or more groups on a dependent variable that is measured on at least an ordinal level. Ordinal data extends beyond rating scores such as the HRSD, and can include ordered categorical variables such as Hollingshead and Redlich's (1958) four broad categories of socioeconomic status. As with the Mann–Whitney test, which is a special two-group case of the Kruskal–Wallis test, the data are pooled (across groups) and ranked from *1* for the lowest value of the dependent variable to *N* for the highest value. In the case of ties, the midpoint is used. For example, if two subjects had the third lowest value, they would each be given a rank of 3.5, the midpoint of 3 and 4. The data from the hypothetical clinical trial comparing CBT, IPT, and MM (originally displayed in Tables 3, 5, and 7, respectively) have been ranked and are presented in Table 10.

After the data have been ranked, the sum of the ranks for each group is calculated:

$$R_j = \sum_{i=1}^{n_j} r_i$$

The mean rank for each of the three groups is then calculated:

$$\bar{r}_j = \frac{\sum_{i=1}^{n_j} r_i}{n_j}$$

The respective rank sums and means for each group are also presented in Table 10. Note that the IPT (18.075) group has a substantially lower mean rank than either the CBT (34.975) or MM (38.45) groups. The Kruskal–Wallis test can be used to determine whether that difference is larger than might be expected by chance. Stated differently, consider an experiment in which 20 numbers are randomly selected from a box that contains 60 balls, numbered 1 though 60. Would it be unlikely to randomly select a group of 20 balls whose sum is 361.5 or lower? Or whose mean is 18.075 or lower? In essence, the Kruskal–Wallis test addresses this question.

Once the ranking has been conducted and the sum of ranks for each group has been determined, the calculations for the Kruskal–Wallis test statistic, *T*, can proceed as follows:

$$T = \frac{(N-1)(S_t^2 - C)}{S_r^2 - C}$$

where

$$S_t^2 = \sum_{i=1}^{k} \frac{R_i^2}{n_i}$$

$$S_r^2 = \sum_{i=1}^{N} r_{ij}^2$$

$$C = \frac{N(N+1)^2}{4}$$

Applying these algorithms to the data that is presented in Table 10:

$$S_t^2 = \sum_{i=1}^{k} \frac{R_i^2}{n_i} = \frac{699.5^2}{20} + \frac{361.5^2}{20} + \frac{769^2}{20}$$
$$= 60567.175$$

$$S_r^2 = \sum_{i=1}^{N} r_{ij}^2$$
$$= 1^2 + 2^2 + 3^2 + ... + 56^2 + 59^2 + 59^2$$
$$= 73587$$

$$C = \frac{N(N+1)^2}{4} = \frac{60(60+1)^2}{4} = 55815$$

$$T = \frac{(N-1)(S_t^2 - C)}{S_r^2 - C}$$
$$= \frac{(60-1)(60567.175 - 55815)}{73587 - 55815} = 15.776$$

Table 10 HRSD for 60 patients in the clinical trial of CBT, IPT, and MM: raw (X_{ij}) and ranked (R_{ij}) values.

	CBT		*IPT*		*MM*	
	X_{ij}	R_{ij}	X_{ij}	R_{ij}	X_{ij}	R_{ij}

	29	57	19	30	31	59.5
	29	57	19	30	31	59.5
Total	420	699.5	301	361.5	445	769
$\bar{R}$		34.975		18.075		38.45

Assumptions of the Kruskal–Wallis test include:

(i) The samples are independent random samples from their respective populations.

(ii) The scale of measurement (of the dependent variable) is at least ordinal.

The hypothesis testing steps for the Kruskal–Wallis test are as follows:

(i) State research question. Do CBT, IPT, and MM have similar effects for the treatment of patients with depression?

(ii) State two mutually exclusive and exhaustive hypotheses with regard to group medians:

(a) $H_0 : M_1 = M_2 = M_3$

(b) $H_A : M_1 \neq M_2 \neq M_3$

(iii) Use the Kruskal–Wallis test to evaluate the hypotheses.

(iv) The critical value for the Kruskal–Wallis test comparing k groups comes from an χ^2 distribution, with $k-1$ degrees of freedom and $\alpha = 0.05$. In this case there are three groups ($k = 3$) and df $= 3-1 = 2$. Therefore, the critical $\chi^2_{(2,.05)} = 5.99$. If $T_{\text{observed}} > 5.99$, reject H_0

(v) Data are displayed in Table 10 for the three groups.

(vi) Calculations are described above.

(vii) Decision regarding H_0. $T_{\text{observed}} > \chi^2_{\text{critical}}$ (i.e., $15.77 > 5.99$), thus reject H_0.

(viii) Conclusion. There is a significant difference in severity of depression among the treatments. (Which groups actually differ can only be determined using an appropriate *post hoc* test, as discussed below.)

This significant result in a Kruskal–Wallis test indicates that there are group differences, but does not indicate which groups differ. As with an ANOVA, a *post hoc* procedure that is analogous to the HSD for ANOVAs can be used to determine which groups are significantly different from each other. That procedure, which will not be discussed here, is described in detail by Conover (1980). Note that in this case, the Kruskal–Wallis results are similar to those of the ANOVA. This is not always the case. The choice between the two tests should be based on whether or not the assumptions of the test are fulfilled and *not* on a comparison of their results. When the results from an ANOVA and a Kruskal–Wallis test conflict, the degree of discrepancy between the two tests may, in part, reflect the extent to which the assumptions were fulfilled.

3.12.4.3.6 Factorial analysis of variance

The fixed effect ANOVA model that was just discussed can be extended to include more than one independent variable. Consider a clinical trial in which the two treatments (CBT and IPT) were compared among samples of two types of mood disorders (major depressive disorder and dysthymia). In such a design the two fixed *factors* (independent variables) are treatment and diagnosis, which each have two *levels*. The two-way ANOVA is used to test *main effects* of each independent variable and the *interaction* between the independent variables. The null hypotheses are:

Main effect of treatment	$H_0 : \mu_{1.} = \mu_{2.}$
Main effect of diagnosis	$H_0 : \mu_{.1} = \mu_{.2}$
Treatment by diagnosis interaction	$H_0 : \mu_{11} - \mu_{12} = \mu_{21} - \mu_{22}$

Note that the first subscript represents treatment level (where 1 = CBT and 2 = IPT), the second subscript represents diagnosis (where 1 = dysthymia and 2 = MDD). In the null hypotheses for the main effects, a dot (.) in the subscript indicates that the corresponding particular variable is ignored. These three null hypotheses are tested with data from one experiment. The *two* main effects in this two-way ANOVA represent an extension of the one main effect that is tested in a one-way ANOVA model described earlier. What is more novel about a *factorial* ANOVA design is the interaction between the factors, which is used to examine the moderating effect one factor has on the effect that the other factor has on the dependent variable. In the hypothetical study presented here, an interaction is used to compare treatment differences (CBT vs. IPT) across diagnostic groups. Stated differently, it is used to examine whether there is a larger difference between IPT and CBT for subjects with MDD or for subjects with dysthymia.

The data from the clinical trial shown earlier in Tables 3 and 5 have been stratified by diagnosis and are presented in Table 11. In a simple comparison of the means, it is clear that the IPT group has a substantially lower mean than the CBT group. Likewise, the dysthymia group has a lower mean than the MDD group. In both cases, the differences are of the order of one standard deviation. The factorial ANOVA is used to evaluate whether or not these differences are larger than might be expected by chance. Furthermore, the ANOVA will be used to compare the treatment effects across diagnostic groups.

The calculations for a two-way factorial ANOVA involve partitioning the total sums of squares into four components: SS_{Tx}, SS_{Dx}, SS_{TxbyDx}, SS_{within}. The algorithms are described in Table 12 and illustrated in Table 13. Note that the subscript g represents treatment ($g = 1,2$), the subscript h represents diagnosis ($h = 1,2$), and the subscript i represents individual subject ($i = 1$–N; $N = 40$ in this case). The formulae that are presented are applicable for designs with cells of equal size (n; $n = 10$ in this case) and are presented to illustrate the concept of the partitioning of sums of squares in a two-way ANOVA. Notice that each estimates a different form of sum of squared deviations (SS) from a mean that represents a component of the variability among the HRSD of all subjects in the clinical trial.

In order to conduct the F-tests of the ANOVA that correspond to the three null hypotheses, several additional calculations are required. The algorithms for these quantities are presented in Table 12. The first column of the table indicates the *source of variability*. The second column displays the SS (calculated above) that correspond to each of the four sources of variability. The third column of Table 12 presents the degrees of freedom that correspond to each source of variability. The calculation of degrees of freedom is described in Table 12. The fourth column in Table 12 presents the mean square (*MS*) for each source of variability which is equal to the sum of squares for that source divided by the corresponding degrees of freedom. In the final column of Table 12, the F-test for each effect is equal to the mean squares for that effect divided by the mean square within (MS_{within}). The results of the data from the example are shown in Table 13.

Assumptions of the factorial ANOVA are as follows:

(i) The observations in each of the cells are independent samples.

(ii) The population data are normally distributed.

(iii) The populations all have equal variances.

The hypothesis testing steps for the factorial ANOVA are as follows:

(i) State research questions.

(a) Do CBT and IPT have similar effects on depressive symptomatology for the treatment of patients with depression?

(b) Do patients with major depressive disorder and dysthymia have similar depressive symptomatology after the treatment of depression?

(c) Do CBT and IPT have similar effects on depressive symptomatology for patients with major depressive disorder and dysthymia?

(ii) State sets of mutually exclusive and exhaustive hypotheses:

(a) Main effect of treatment

$H_0 : \mu_{1\cdot} = \mu_{2\cdot}$

$H_A : \mu_{1\cdot} \neq \mu_{2\cdot}$

(b) Main effect of diagnosis

$H_0 : \mu_{\cdot 1} = \mu_{\cdot 2}$

$H_A : \mu_{\cdot 1} \neq \mu_{\cdot 2}$

(c) Interaction of treatment by diagnosis

$H_0: \mu_{11} - \mu_{21} = \mu_{12} - \mu_{22}$

$H_A: \mu_{11} - \mu_{21} = \mu_{12} - \mu_{22}$

(iii) If assumptions have been fulfilled, use the two-way factorial ANOVA to evaluate the hypotheses.

(iv) The critical F-values are selected from an F-table based on the degrees of freedom numerator, degrees of freedom denominator, and alpha-level. The critical value for the F-test with $\alpha = 0.05$ and $df = 1,36$ is 5.47. Reject H_0 if $F_{\text{observed}} > F_{\text{critical}}$.

(v) Data are displayed in Table 11.

(vi) Calculations are described above.

(vii) Decisions regarding the three H_0s.

(a) Main effect of treatment

The main effect of treatment is statistically significant:

$F_{\text{obs}} > F_{\text{critical}(1,36;.05)}$ (i.e., $17.114 > 5.47$).

(b) Main effect of diagnosis

The main effect of diagnosis is statistically significant:

$F_{\text{obs}} > F_{\text{critical}(1,36;.05)}$ (i.e., $14.359 > 5.47$).

(c) Interaction of treatment by diagnosis

The treatment by diagnosis interaction is not statistically significant:

$F_{\text{obs}} < F_{\text{critical}(1,36;.05)}$ (i.e., $0.639 < 5.47$).

(viii) Conclusion. IPT is a significantly more effective treatment than CBT for depressive symptoms. Patients with major depressive disorder have significantly more depressive symptomatology than those with dysthymia after treatment. The differential effects of IPT and CBT are similar for patients with major depressive disorder and patients with dysthymia.

In this case, *post hoc* tests such as those described earlier are not needed to interpret these results because there are only two levels of each significant factor and there is not a significant interaction. To determine which level of each factor had a better outcome in this clinical trial, simply compare the means of each level of the significant effects and determine which is lower (i.e., less depressed on the HRSD). For the treatment effect, the IPT group mean (sd) is substantially lower than that of the CBT group: 15.05 (4.67) vs. 21.00 (5.80). The two groups differ by more than one standard deviation, which is a very large difference. Similarly, the dysthymia group mean (sd) is substantially lower than that of the MDD group: 15.30 (5.57) vs. 20.75 (5.24). Here the groups differ by slightly less than one standard deviation, which is

Table 11 Hamilton Depression Ratings for 40 patients in the clinical trial of CBT and IPT stratified by diagnosis.

Table 12 Two-way ANOVA table.

Source	*SS*	*df*	*MS*	*F*
Treatment	SS_{Tx}	$p-1$	$\text{SS}_{\text{Tx}}/(p-1)$	$\text{MS}_{\text{Tx}}/\text{MS}_{\text{within}}$
Diagnosis	SS_{Dx}	$q-1$	$\text{SS}_{\text{Dx}}/(q-1)$	$\text{MS}_{\text{Dx}}/\text{MS}_{\text{within}}$
Tx by dx	$\text{SS}_{\text{Tx by Dx}}$	$(p-1)(q-1)$	$\text{SS}_{\text{Tx by dx}}/(p-1)(q-1)$	$\text{MS}_{\text{Tx by dx}}/\text{MS}_{\text{within}}$
Within	$\text{SS}_{\text{within}}$	$pq(n-1)$	$\text{SS}_{\text{within}}/pq(n-1)$	
Total	SS_{Total}	$n-1$		

$$\text{SS}_{\text{Total}} = \sum_{i=1}^{N}(X_{ghi} - \bar{X}...)^2$$

$$\text{SS}_{\text{T}_{\text{X}}} = nq\sum_{j=1}^{p}(\bar{X}_{g..} - \bar{X}...)^2$$

$$\text{SS}_{\text{D}_{\text{X}}} = np\sum_{k=1}^{q}(\bar{X}_{.h.} - \bar{X}_{...})^2$$

$$\text{SS}_{\text{TxbyDx}} = n\sum_{g=1}^{p}\sum_{h=1}^{q}\left[(\bar{X}_{gh.} - \bar{X}_{...}) - (\bar{X}_{g..} - \bar{X}_{...}) - (\bar{X}_{.h.} - \bar{X}_{...})\right]^2$$

$$\text{SS}_{\text{Within}} = \sum_{g=1}^{p}\sum_{h=1}^{q}\sum_{i=1}^{n}(\bar{X}_{ghi} - \bar{X}_{gh.})^2$$

again a substantial difference. In contrast, the interaction was not significant. Consider the differences in treatment means across diagnoses:

$$\bar{X}_{CBT/DYS} - \bar{X}_{IPT/DYS} = 17.70 - 12.90 = 4.80$$

and

$$\bar{X}_{CBT/MDD} - \bar{X}_{IPT/MDD} = 24.30 - 17.20 = 7.10$$

Relative to the variation within treatment (marginal standard deviations range from 4.67 to 5.80), the difference in mean differences (7.10 − 4.80 = 2.30), is not substantial enough to consider it more than might be expected by chance.

The *two-way factorial ANOVA* example that was just discussed included two factors (i.e., independent variables: treatment and diagnosis), each of which had two levels. The factorial ANOVA can incorporate factors which have more than two levels each. This was shown in the earlier example of the one-way ANOVA in which there were three levels of treatment (CBT, IPT, and MM). In addition, the factorial design can be extended to include more than two factors. For instance, the clinical trial could have been conducted to test the effect of gender as well as treatment and diagnosis. Such a design is called a *three-way ANOVA*, which includes tests of three main effects (treatment, diagnosis, and gender), three two-way interactions (treatment by diagnosis, treatment by gender, and diagnosis by gender), and one three-way interaction (treatment by diagnosis by gender). For an extensive discussion of ANOVA designs see Keppel (1991).

In this chapter, two multivariate statistical procedures will be introduced, but not discussed in depth. For a comprehensive discussion of these and other multivariate tests, see Bock (1985), Grimm and Yarnold (1995), Marcoulides and Hershberger (1997), or Stevens (1992). Here multivariate means that multiple dependent variables are being examined in one test. For instance, consider the comparison of affectively ill patients with schizophrenic patients on a battery of six personality scales. There are two schools of thought for use of a multivariate procedure such as this. One is that it should be used if there is a multivariate research question. For example, do the personalities of the two diagnostic groups differ as a whole? The researcher who asks this question, might be most interested in personality as a general construct, and less interested in the specific differences in ego resiliency, dependency and other personality characteristics. In contrast, others would argue that the multivariate procedures should be used to protect against Type I error whenever several dependent variables are examined.

&= 744.70
\end{aligned}$$

3.12.4.3.7 Hotelling's T^2

Hotelling's T^2 is used to compare two groups on multiple continuous dependent variables, simultaneously. Consider that if a series of six univariate *t*-tests were performed on these scales, the probability of a Type I error would be substantially elevated from the conventional 0.05 level. In general, the experimentwise alpha level for *c* comparisons is calculated as follows: $\alpha_{\mathrm{EW}} = 1-(1-\alpha)^c$. Thus, in lieu of a multivariate procedure, the two groups might be compared using six univariate *t*-tests (one for each of the six dependent variables—the personality scales) and the resulting experimentwise alpha level would be $\alpha_{\mathrm{EW}} = 1-(1-0.05)^6 = 1-0.735 = 0.265$, which certainly exceeds the conventional Type I error level of 0.05.

Although the computational details of Hotelling's T^2 are beyond the scope of this chapter, some general issues regarding the procedure will be introduced. First, the null hypothesis is that the populations from which the two groups come do not differ on (a linear combination) of the scales (see below). Second, assumptions of Hotelling's T^2 include multivariate normality and independence of observations across subjects. Third, Hotelling's T^2 is an omnibus multivariate procedure. If, and only if, the multivariate null hypothesis is rejected, can subsequent *post hoc* univariate tests be used to identify the source of the difference (i.e., on which dependent variable(s) do the groups differ?). This is similar to the approach to the comparison of three or more groups in an ANOVA where, if the omnibus *F*-test is significant, a *post hoc* test must be used to determine which groups differ significantly. However, those *post hoc* tests cannot be used if the omnibus *F* of the univariate ANOVA is not significant. In the case of Hotelling's T^2, the *post hoc* tests would simply be a *t*-test for each dependent variable.

The hypothesis testing steps for Hotelling's T^2 are as follows:

(i) State research question. Are the personality profiles of affectively ill patients and schizophrenic patients similar (using a battery of six personality scales)?

(ii) State two mutually exclusive and exhaustive hypotheses:

$$H_0 : \begin{bmatrix}\mu_{11}\\ \mu_{21}\\ \mu_{31}\\ \mu_{41}\\ \mu_{51}\\ \mu_{61}\end{bmatrix} = \begin{bmatrix}\mu_{12}\\ \mu_{22}\\ \mu_{32}\\ \mu_{42}\\ \mu_{52}\\ \mu_{62}\end{bmatrix}$$

$$H_A : \begin{bmatrix}\mu_{11}\\ \mu_{21}\\ \mu_{31}\\ \mu_{41}\\ \mu_{51}\\ \mu_{61}\end{bmatrix} \neq \begin{bmatrix}\mu_{12}\\ \mu_{22}\\ \mu_{32}\\ \mu_{42}\\ \mu_{52}\\ \mu_{62}\end{bmatrix}$$

(iii) If the assumptions are met, use the Hotelling's T^2 evaluate the hypotheses.

(iv) The critical value, calculations, decision rules, and interpretation of Hotelling's T^2 are described elsewhere (e.g., Stevens (1992) or Marcoulides & Hershberger (1997)).

3.12.4.3.8 Multivariate analysis of variance

Multivariate analysis of variance (MANOVA) is an extension of the T^2 for the comparison of three or more groups. For example, three groups (e.g., mood disorders, schizophrenics, and no history of a mental disorder) can be compared on a battery of six personality scales using a MANOVA. Similar to the factorial ANOVA, MANOVA can also be extended to incorporate more than one factor. For instance, a two-way MANOVA could evaluate the main effects and interaction of gender and diagnosis (mood disorders vs. schizophrenics vs. no history of a mental disorder) in which the dependent variables are a battery of six personality scales. If any of those three omnibus multivariate tests (i.e, main effects of gender or diagnosis or the gender by diagnosis interaction) are statistically significant, subsequent *post hoc* tests must be conducted to determine the source of the group differences. The choice among multivariate test statistics (e.g., Pillais, Hotelling's, Wilks, or Roy) is considered by Olson (1976). *Post hoc* tests for MANOVA are described in detail by Stevens (1992).

Assumptions of MANOVA include:

(i) independence among observations (i.e., subjects)

(ii) a multivariate normal distribution among the dependent variables

(iii) equal population covariance matrices for the dependent variables.

The hypothesis testing steps for MANOVA are as follows:

(i) State research question. Are the personality profiles of affectively ill patients, schizophrenic patients, and those with no history of mental disorders similar (using a battery of six personality scales)?

(ii) State two mutually exclusive and exhaustive hypotheses:

$$H_0: \begin{bmatrix} \mu_{11} \\ \mu_{21} \\ \mu_{31} \\ \mu_{41} \\ \mu_{51} \\ \mu_{61} \end{bmatrix} = \begin{bmatrix} \mu_{12} \\ \mu_{22} \\ \mu_{32} \\ \mu_{42} \\ \mu_{52} \\ \mu_{62} \end{bmatrix} = \begin{bmatrix} \mu_{13} \\ \mu_{23} \\ \mu_{33} \\ \mu_{43} \\ \mu_{53} \\ \mu_{63} \end{bmatrix}$$

$$H_A: \begin{bmatrix} \mu_{11} \\ \mu_{21} \\ \mu_{31} \\ \mu_{41} \\ \mu_{51} \\ \mu_{61} \end{bmatrix} \neq \begin{bmatrix} \mu_{12} \\ \mu_{22} \\ \mu_{32} \\ \mu_{42} \\ \mu_{52} \\ \mu_{62} \end{bmatrix} \neq \begin{bmatrix} \mu_{13} \\ \mu_{23} \\ \mu_{33} \\ \mu_{43} \\ \mu_{53} \\ \mu_{63} \end{bmatrix}$$

(iii) If the assumptions are met, use a MANOVA to evaluate the hypotheses.

(iv) The critical value, calculations, decision rules, and interpretation of MANOVA are described elsewhere (e.g., Marcoulides & Hershberger, 1997; Pedhazur, 1982; Stevens, 1992).

3.12.4.4 Linear Relations

3.12.4.4.1 Pearson correlation coefficient

The strength of the bivariate linear relation between variables can be examined with a correlation coefficient. The Pearson product moment correlation coefficient, r, is most often used for this purpose. In correlational analyses, a distinction need not be made between the independent and dependent variables. Unlike the univariate analyses that were discussed earlier, each subject contributes data in the form of paired coordinates (x, y) to the analysis.

Consider the data in Figure 12 which represents the relation between depression (on the x-axis) and functional impairment (on the y-axis). (These same data are presented in the first two columns of Table 14.) If there were even a modest linear relation between depression and functional impairment, one would expect minimal impairment in the mildly depressed and greater impairment in the severely depressed. It is a correlation coefficient that quantifies the strength of that linear relationship. (Once again, as a point of clarification, unlike much of the prior discussion in this chapter, here we consider two variables from one group of subjects.)

A brief digression may help with this explanation. It is quite likely that the two variables in a correlational analysis are measured on very different scales. For instance, in this sample, the impairment and depression means (21.00 and 14.45, respectively) and standard deviations (5.80 and 4.93, respectively) differ somewhat. For that reason, consider a scale-free metric, a standardized score, referred to as a "z-score," which has the property of a mean of zero and standard deviation of one. A transformation from the original scale (X_i) to the standardized scale (Z_i) is quite simple. The original variable (X_i) is transformed by subtracting the mean and dividing by the standard deviation:

Table 14 Hamilton depression ratings and Sheehan Disability Scale for CBT group.

	X_i	Y_i	X_i^2	Y_i^2	X_iY_i	$X_i - \bar{X}$	$Y_i - \bar{Y}$	$(X_i - \bar{X})^2$	$(Y_i - \bar{Y})^2$	$x \cdot y$	z_x	z_y	$Z_x \cdot Z_y$

$x_i = X_i - \bar{X}$; $y_i = Y_i - \bar{Y}$; $Z_{x_i} = \frac{X_i - \bar{X}}{s_x}$; $Z_{y_i} = \frac{Y_i - \bar{Y}}{s_y}$.

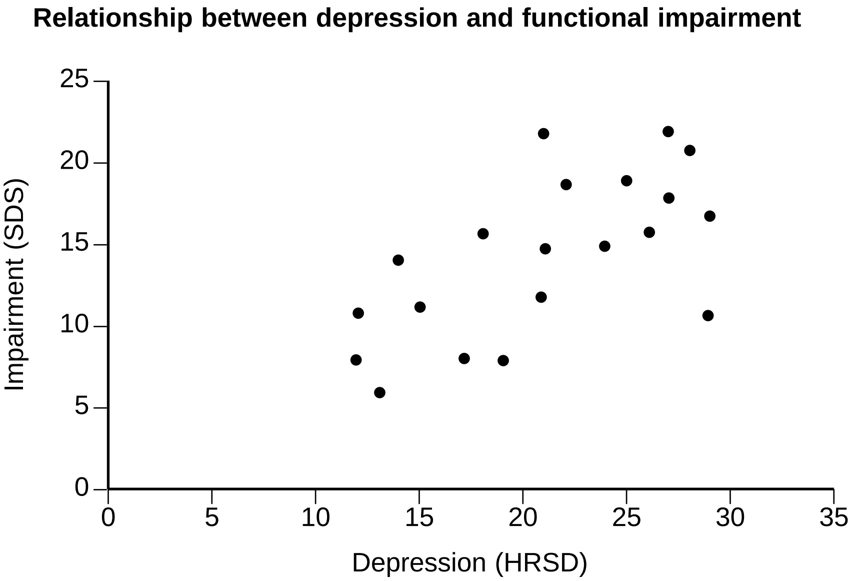

Figure 12 Plot of Hamilton Depression Ratings and Sheehan Disability Scale for CBT group.

$$Z_i = \frac{X_i - \bar{X}}{s_x}$$

The plot of standardized depression and functional impairment in Figure 13 looks identical to that of Figure 12, with the exception of the scale of the axes. (Note that in order to distinguish between the standardized X_is and standardized Y_is, Xs and Ys will be included in the subscript of the standardized scores: Z_{xi} and Z_{yi}.) As a consequence of the standardization, the Z_x-axis is plotted at $Y = 0$, which is the unstandardized y-mean, and the Z_y-axis is plotted at $X = 0$, the unstandardized x-mean.

As stated earlier, if there were a modest linear relation between depression and impairment, there would be minimal impairment in the mildly depressed and greater impairment in the severely depressed. Consider this positive linear relationship as presented in Figure 12. The points that are plotted tend to cluster either in quadrant I or in quadrant III. The latter fall in the upper-right quadrant, where subjects tend to have both relatively elevated depression and relatively elevated functional impairment. Stated differently, both the x-values and y-values are above the mean in Figure 12, and the standardized z_x and z_y scores are both positive in Figure 13. On the other hand, the subjects who have both relatively lower depression and relatively lower functional impairment are in the lower-left quadrant. That is, both the x-values and y-values are below the mean. In contrast, a negative linear relationship would characterize an association in which a high x-value tends to correspond with a low y-value, and a low x-value corresponds with a high y-value (e.g., depression and work productivity). Nunnally (1978) shows that the Pearson r can be calculated as approximately the mean of the sum of the product of z-scores:

$$r_{xy} = \frac{\sum_{i=1}^{N} Z_x Z_y}{N - 1}$$

With this algorithm it can be seen that if most subjects tend to have either high Z_xs and high Z_ys, or low Z_xs and low Z_ys, r will be larger and positive, approaching 1.0. In contrast, if most subjects tend to have either high Z_xs with low Z_ys, or low Z_xs with high Z_ys, r will have a large absolute value, but will be negative, approaching -1.0.

Using the data that are presented in Table 14:

$$r = \frac{\sum_{i=1}^{N} z_x z_y}{N - 1} = \frac{12.31}{20 - 1} = 0.648$$

The presentation of the algorithm for the Pearson correlation coefficient (r) usually comes from a seemingly different perspective which will now be discussed. The correlation coefficient is derived from the covariance. First, consider that the sum of cross-products ($\sum xy$) is a sum of the product of both the x-deviations (x) and y-deviations (y) from their respective means: $\sum xy = \sum (X_i - \bar{X})(Y_i - \bar{Y})$.

For instance, the first subject in Table 14 has an X-value (HRSD) of 12 and a Y-value (SDS) of 11. The respective deviation scores are:

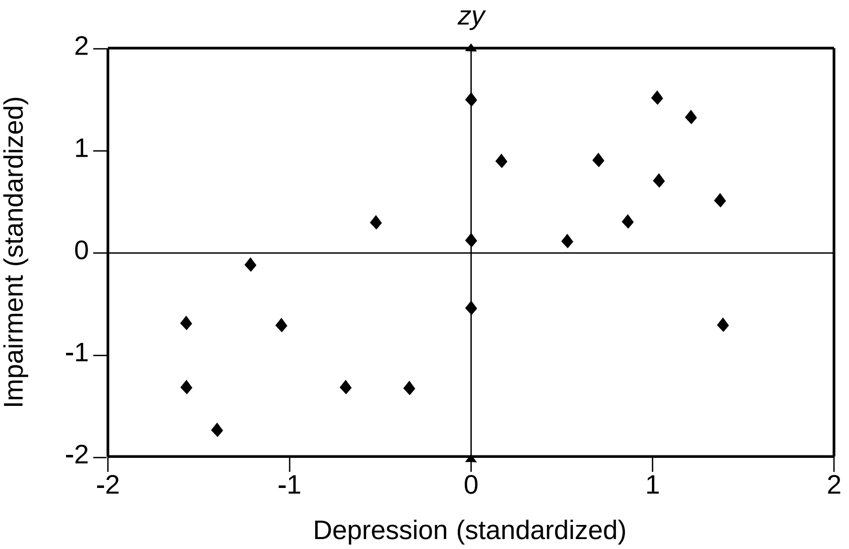

Figure 13 Plot of standardized Hamilton Depression Ratings and standardized Sheehan Disability Scale for subjects in the CBT group ($N = 20$).

$$x_1 = X_1 - \bar{X} = 12 - 21 = -9$$
$$y_1 = Y_1 - \bar{Y} = 11 - 14.45 = -3.45$$

The product of the deviation scores is called the cross-product. For the first subject, the cross-product is:

$$x_1 y_1 = -9 \cdot (-3.45) = 31.05$$

Once again, the sum of cross-products $(\sum_{i=1}^{N} x_i y_i)$ or $(\sum xy)$ is a sum of each subject's product of deviation scores. Notice that the sum of cross-products is a bivariate extension of the sum of squares that was described earlier, but the sum of cross-products incorporates two variables:

$$\sum x^2 = \sum (X_i - \bar{X})(X_i - \bar{X})$$

The covariance (s_{xy}), therefore, is a bivariate analogue of the variance. Consequently, the covariance is a function of the sum of cross-products:

$$s_{xy} = \frac{\sum xy}{n-1}$$

Using the equations above, the covariance (s_{xy}) can also be calculated:

$$s_{xy} = \frac{\sum (X_i - \bar{X})(Y_i - \bar{Y})}{n-1}$$

The covariance (s_{xy}) is a useful quantity that also measures the strength of the linear relationship between two variables. However, its interpretability is somewhat limited because it is not scale-free. As a consequence, unlike the correlation coefficient (r), which ranges from negative to positive (i.e., $-1.0 \leqslant r \leqslant 1.0$), the covariance does not have a fixed range.

Notice that the variance of a variable can be thought of as a special case of the covariance of that variable with itself: $S_{xx} = \sum (X_i - \bar{X})(X_i - \bar{X})$. A variance–covariance matrix is a convenient format to display the variances and covariances among several variables:

$$\begin{array}{cccc} & X & Y & Z \\ X & s_X^2 & s_{XY} & s_{XZ} \\ Y & s_{YX} & s_Y^2 & s_{YZ} \\ Z & s_{ZX} & s_{ZY} & s_Z^2 \end{array}$$

The variances are on the main diagonal and the covariances are the remaining elements of the matrix. The matrix is symmetrical about the main diagonal. That is, in general, $s_{ij} = s_{ji}$. Or in the case, $s_{XY} = s_{YX}$.

Using the data from Table 14, the covariance is:

$$S_{xy} = \frac{\sum xy}{n-1} = \frac{\sum_{i=1}^{n} (X_i - \bar{X})(Y_i - \bar{Y})}{n-1}$$
$$= \frac{352}{20-1} = 18.526$$

Turning back to the correlation coefficient, r can be calculated using these quantities. It is equal to the covariance (s_{xy}) of X_i and Y_i, divided by the product of their standard deviations:

$$r_{XY} = \frac{S_{XY}}{S_X S_Y} = \frac{18.526}{5.803 \cdot 4.925} = 0.648$$

As stated earlier, the correlation coefficient (r) can range from -1 to $+1$. The greater the absolute value of r, the greater the strength of the bivariate linear relationship.

The statistical significance of the population correlation coefficient, ρ, can be tested using the sample data. The null hypothesis, H_0:$\rho = 0$, is tested with the following ratio:

$$t = \frac{r}{s_r}$$

where s_r is the standard error of r,

$$s_r = \sqrt{\frac{1 - r^2}{n - 2}}$$

This t-ratio is tested with $n-2$ dfs. Applying this to the data from Table 14, the standard error of r is:

$$s_r = \sqrt{\frac{1 - r^2}{n - 2}} = \sqrt{\frac{1 - 0.648^2}{20 - 2}} = 0.1795$$

The t-ratio is:

$$t = \frac{r}{s_r} = \frac{0.648}{0.1795} = 3.61$$

The hypothesis testing steps for the Pearson correlation coefficient are as follows:

(i) State research question. Is there a linear relationship between depression and impairment?

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) $H_0: \rho_{XY} = 0$

(b) $H_A: \rho_{XY} \neq 0$

(iii) Choose the t-ratio to evaluate the hypotheses about the Pearson correlation coefficient.

(iv) The critical value for the t-ratio with $\alpha = 0.05$ and $\text{df} = 18$ is 2.101. If $t_{\text{observed}} > t_{\text{critical}}$, reject H_0.

(v) Data regarding depression and impairment are displayed in Table 14.

(vi) Calculations were described above.

(vii) Decision regarding H_0. Since $t_{\text{observed}} > t_{\text{critical}}$ (i.e., $3.61 > 2.101$), reject H_0.

(viii) Conclusion. Based on data from this sample, we conclude that there is a statistically significant linear relationship between depression and impairment.

Although the null hypothesis, H_0: $\rho = 0$, was rejected, be cautious not to overinterpret the results of such a test. The hypothesis simply examines the likelihood of observing a correlation of the *magnitude* seen in the sample, when the population correlation is zero (i.e., $\rho = 0$). Nevertheless, it ignores the meaningfulness of the magnitude of r. There is a disproportionate emphasis on the *statistical significance* of r while at the same time a tendency to ignore the *magnitude* of r in the research literature.

The magnitude of the correlation can be thought of as the proportion of variance in Y_i explained by X_i. In fact, because in correlational analyses a distinction between independent variable and dependent variable is unnecessary, the magnitude of the correlation can also be thought of as the proportion of variance in X_i explained by Y_i. In either case, the magnitude of the correlation coefficient r is calculated as the squared correlation coefficient, r^2, or, more commonly, R^2. Since the variability in human behavior and affect are not easily explained, meaningful R^2s in behavioral sciences can be quite small ($R^2 < 0.10$) and an $R^2 > 0.20$ may be considered substantial. Using the data from the *hypothetical* example in Table 14, 42% of the variance in functional impairment is explained by depression (i.e., $R^2 = r^2 = 0.648^2 = 0.420$).

3.12.4.4.2 Test for a difference between two independent correlation coefficients

The correlation coefficients of two groups can be compared by testing the following null hypothesis:

$$H_0\text{: } \rho_1 = \rho_2$$

The test is conducted in the following manner. First, each correlation coefficient (r_k) is transformed into a Z_k using a procedure called the r_k to Z_k transformation. Note that the subscript k represents group k. Unlike earlier notation, in this context the subscript is not used to differentiate among subjects.

$$Z_k = 0.5 \cdot \ln\left(\frac{1 + r_k}{1 - r_k}\right)$$

where $k = 1$ or 2 and ln represents the natural logarithm.

Next a standard error is calculated:

$$\rho_{z_1 - z_2} = \sqrt{\frac{1}{n_1 - 3} + \frac{1}{n_2 - 3}}$$

Finally, the Z-statistic is calculated:

$$Z = \frac{Z_1 - Z_2}{\sigma_{z_1 - z_2}}$$

For example, this could be used to address the question, "Is the strength of the linear relation between depression and functional impairment different in the subjects in the CBT and IPT groups?" Although IPT impairment data are not presented in a table, for illustration assume that for the IPT group $r = 0.41$. Comparison of the correlation coefficients for the CBT and IPT groups proceeds as follows:

$$Z_1 = 0.5 \cdot \ln\left(\frac{1+\mathrm{r}_1}{1-\mathrm{r}_1}\right) = 0.5 \cdot \ln\left(\frac{1+.648}{1-.648}\right)$$
$$= .772$$
$$Z_2 = 0.5 \cdot \ln\left(\frac{1+\mathrm{r}_2}{1-\mathrm{r}_2}\right) = 0.5 \cdot \ln\left(\frac{1+.41}{1-.41}\right)$$
$$= .436$$
$$\sigma_{z_1-z_2} = \sqrt{\frac{1}{n_1-3}+\frac{1}{n_2-3}}$$
$$= \sqrt{\frac{1}{20-3}+\frac{1}{20-3}} = .343$$
$$Z = \frac{Z_1-Z_2}{\sigma_{z_1-z_2}} = \frac{.772-.436}{.343} = .980$$

The assumptions of the Z-test of correlation coefficients across two groups is that X and Y come from a bivariate normal distribution. What this means is that, if X comes from a normal distribution, and Y is normally distributed at every value of X.

The hypothesis testing steps for the Z-test to compare correlation coefficients across two groups are as follows:

(i) State research question. Is the strength of the linear relation between depression and functional impairment different for subjects in the CBT and IPT groups?

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) $H_0: \rho_1 = \rho_2$

(b) $H_A: \rho_1 \neq \rho_2$

(iii) Choose the Z-test to evaluate the hypotheses.

(iv) The critical value for the Z-test with $\alpha = 0.05$ is 1.96. If $z_{\text{observed}} > z_{\text{critical}}$, reject H_0.

(v) Data are displayed in Table 14 for the CBT group. The correlation for the IPT group was specified in the text as $r = 0.41$.

(vi) Calculations were described above.

(vii) Decision regarding H_0. Since $z_{\text{observed}} < z_{\text{critical}}$ (i.e., $.980 < 1.96$), do not reject H_0.

(viii) Conclusion. There is not a statistically significant difference in the strength of the linear relationship between depression and impairment for those in the CBT and IPT groups in this study of treatment of depressive symptoms in patients with major depressive disorder.

There are several more points regarding the Pearson r that will be discussed briefly. First, the correlation of a *variable* with a *constant* is zero. One of the methods of calculating r that was described above includes the covariance (s_{xy}) in the numerator. Recall that the covariance is equal to the sum of cross-products over $N-1$. Also, recall that the sum of the cross-products: $\sum xy = \sum(X_i - \bar{X})(Y_i - \bar{Y})$. If Y_i is a constant, then for each subject $Y_i = \bar{Y}$ and thus the sum of cross-products is also equal to zero:

$$\sum xy = \sum(X_i - \bar{X})(Y_i - \bar{Y})$$
$$= \sum(X_i - \bar{X}) \cdot 0 = 0$$

If the covariance is equal to zero, $r = 0$.

There is another useful fact about how r is affected by a constant (c_i). If the correlation between depression (X_i) and impairment (Y_i) is r_{xy}, and a constant is added to either X_i or Y_i, the correlation is not affected. For instance, say that the 24-item HRSD ratings were to be collected for all acutely suicidal subjects in a study. However, in the interest of time the HRSD suicide item was not scored and not included in a modified HRSD 23-item total, call it Y_{M_i}. Technically, all of these subjects, being acutely suicidal would rate 2 on the HRSD suicide item. Thus a 24-item total, Y_i, could be calculated for each subject simply by adding 2 to the subject's 23-item total. The addition of a constant (c_i) to a variable (Y_i) increases the value of the y-mean by c_i (i.e., $\bar{Y}_M = \bar{Y} + c_i$) and it does not affect the standard deviation (i.e., $S_{Y_M} = S_Y$). As a consequence neither the covariance (s_{xy}) nor the sum of cross-products $\sum xy$ is changed, and thus the correlation coefficient is not affected: $r_{xy} = r_{xy_M}$.

Finally, correlation coefficients for pairs of several variables (x, y, and z) can be conveniently presented in the form of a correlation matrix:

$$\begin{array}{cccc} & X & Y & Z \\ X & 1.0 & r_{XY} & r_{XZ} \\ Y & r_{YX} & 1.0 & r_{YZ} \\ Z & r_{ZX} & r_{ZY} & 1.0 \end{array}$$

Notice that the elements of the correlation matrix are symmetric. That is, the correlation of X_i with Y_i (r_{XY}) is equal to the correlation of Y_i with X_i (r_{YX}). Furthermore, the correlation of a variable (e.g., X_i) with itself is equal to unity. All elements of the main diagonal of a correlation matrix are 1.0: $r_{XX} = r_{YY} = r_{ZZ} = 1.0$.

3.12.4.4.3 Spearman rank correlation

The Spearman rank correlation is a nonparametric correlation coefficient, which is computed using the ranks of the raw data. This is appropriate when the population data are believed to be non-normal. The Spearman rank correlation is especially useful when data contain an outlier (i.e., an extreme value),

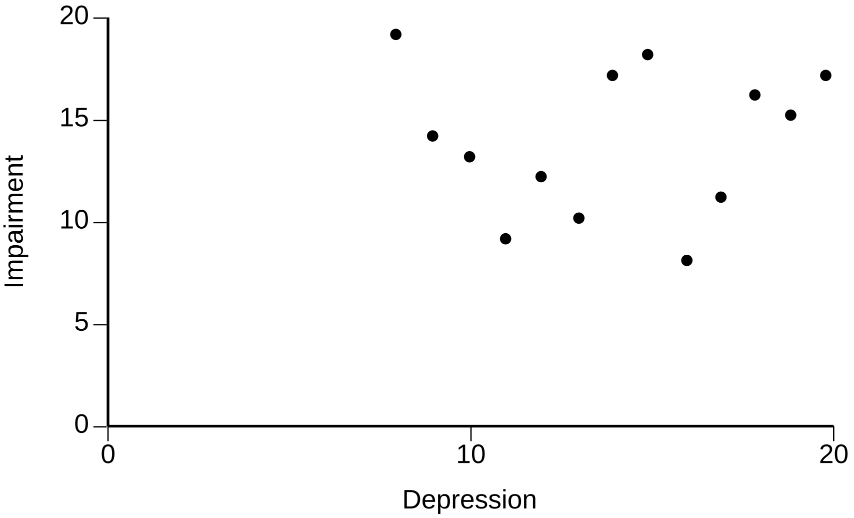

Figure 14 Plot of Hamilton Depression Ratings and Sheehan Disability Scores.

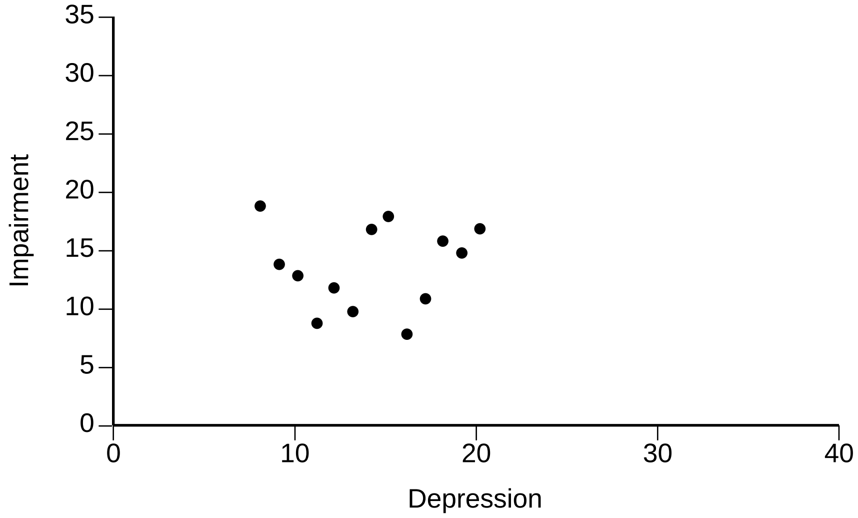

Figure 15 Plot of Hamilton Depression Ratings and Sheehan Disability Scores.

which can strongly, and inappropriately, increase the magnitude of the Pearson correlation coefficient. For instance, compare the plots presented in Figures 14 and 15. The only difference in these plots is that Figure 15 includes one additional case, which is an outlier. That is, the additional case has extreme values on both the x- and y-variables. In Figure 14 there is no linear relationship between depression (X) and impairment (Y). Stated differently, knowledge of the level of depression (X_i) will not help in "guessing" the level of impairment (Y_i). In fact, for the data in Figure 14, the Pearson correlation coefficient between depression and impairment is $r = 0.066$. In stark contrast, with the addition of one outlier, the Pearson correlation coefficient between depression and impairment is $r = 0.697$ for the data in Figure 15. In Figure 15, which includes one outlier, knowledge of the severity of a subject's depression would not help in guessing the corresponding level of impairment.

The discrepancy between these two Pearson correlation coefficients illustrates that the Pearson correlation coefficient can be quite sensitive to an outlier. The influence of outliers on the correlation coefficient can be minimized by calculating the correlation on the rank-transformed data to examine the linear relationship between the ranks of X_i and Y_i. The Spearman rank correlation is used for that purpose.

For example, the data displayed in Figure 15 are presented in Table 15. In addition to the actual depression (X_i) and impairment (Y_i) ratings, the ascending ranks of those ratings are presented in Table 15. The rank transformation procedure was described earlier in this chapter (see discussion of the Mann–Whitney test). Although this is a bivariate analysis, the rankings of the depression (R_{X_i}) and impairment (R_{Y_i}) ratings are performed independently. (The upper-case R is used to represent a ranked variable and is not to be confused with lower-case r, which is generally used to represent a Pearson correlation coefficient.) To calculate the Spearman rank correlation coefficient r_s, the difference (d_i) between the paired ranks for each subject is calculated ($d_i = R_{X_i} - R_{Y_i}$) and squared (d_i^2). The sum of the squared differences in ranks $\sum(d_i^2)$(is used in the calculations of r_s. In the case of no tied ranks, r_s is calculated:

$$r_s = 1 - \frac{6\sum_{i=1}^{N} d_i^2}{n^3 - n} = 1 - \frac{6 \cdot 345}{14^3 - 14} = 0.242$$

Notice that the value of d_i is minimized, and consequently the quantity, $6\sum_{i=1}^{N} d_i^2$ is minimized, as the pairs of ranks of X_i and Y_i for each subject correspond closely. Since the ratio in that equation is subtracted from unity, the value of r_s is closer to 1.0 when that ratio is small; and r_s is closer to zero when the ratio approaches 1.0. Thus, r_s is a quantity that reflects the strength of a linear relationship.

An r_s of .242 is certainly a more reasonable reflection of the strength of the linear relationship between X_i and Y_i in Table 15 than the Pearson r of .697.

The calculations for data involving tied data are more extensive (see, for example, Conover, 1980) and will not be discussed here. Incidentally, the data displayed in Figure 14 come from the first 13 of the 14 subjects that are presented in Table 15. The Pearson and Spearman rank correlation coefficients for the sample of 13 subjects are $r = 0.066$ and $r_s = 0.052$, respectively.

In using the Spearman rank correlation coefficient, it is assumed that the data are randomly sampled, that the subjects are independent, and that the scale of measurement is at least ordinal.

The hypothesis testing steps for the Spearman rank correlation coefficient are as follows:

(i) State research question. Is there a relationship between depression and impairment such that high values of depression tend to be associated with high values of impairment? Alternatively, one might hypothesize that there is a negative relationship between two variables X and Y (i.e., $r_s < 0$), such that high values of X tend to be associated with low values of Y.

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) $H_0 : \rho_{S_{XY}} = 0$

(b) $H_A : \rho_{S_{XY}} \neq 0$

(iii) Use a table of critical values for the Spearman rank correlation coefficient (for example, see Conover, 1980, p. 456). The critical value with a two-tailed $\alpha = 0.05$ and $N = 14$ is 0.534. If $|r_{s_{\text{observed}}}| > r_{s_{\text{critical}}}$, reject H_0.

(iv) Data regarding depression and impairment are displayed in Table 15.

(v) Calculations were described above.

(vi) Decision regarding H_0. Since $|r_{s_{\text{observed}}}| < r_{s_{\text{critical}}}$ (i.e., $0.242 < 0.534$), do not reject H_0.

(viii) Conclusion. Based on data from this sample, we conclude that there is not a statistically significant correlation between depression and impairment.

3.12.4.4.4 Simple linear regression analysis

If a distinction between the independent and dependent variables is made, a correlational analysis can be extended to a *simple linear regression analysis*. In a regression analysis, the dependent variable (y) is regressed on the independent variable (x). Graphically, the x-axis represents the independent variable and the y-axis represents the dependent variable. As in a correlational analysis, each subject contributes data in the form of paired coordinates (x, y) to the regression analysis. The regression equation, $\hat{Y} = a + bX$, includes two variables, Y and X, and two constants, the y-intercept (a) and the slope (b). After the constants have been calculated, the equation can be used to estimate a conditional value of Y. That is, the equation is used to estimate a value of Y, *conditioned* on a value of X (i.e., $Y|X$). The algorithms which are used to estimate the regression constants, a and b, employ the *least-squares criterion*, which minimizes the sum of the squared distances from the observed data (Y_i) and those estimated with the regression equation ($\hat{Y}_i$). $\hat{Y}$ is called *predicted* Y or Y*-hat*. The estimated values of $\hat{Y}$ are points along the regression line, which is defined by the regression equation.

For example, consider the relation between depression (X) and functional impairment (Y), where the latter is the dependent variable. The data from Table 14 are plotted in Figure 16 where depression is measured using the HRSD and functional impairment is measured with the Sheehan Disability Scale. The slope (b) represents the expected change in functional impairment that is associated with a one-unit change in depression. Stated differently, consider two subjects with depression ratings of X_i and $X_i + 1$, respectively. If the former subject has an impairment rating of Y_i, the latter will have

Table 15 Depression (X_i) and impairment (Y_i) ratings of 14 patients with affective symptomatology.

X_i	$Rank(X_i)$	Y_i	$Rank(Y_i)$	d_i	d_i^2
8	1	19	13	−12	144
9	2	14	7	−5	25
10	3	13	6	−3	9
11	4	9	2	2	4
12	5	12	5	0	0
13	6	10	3	3	9
14	7	17	10	−3	9
15	8	18	12	−4	16
16	9	8	1	8	64
17	10	11	4	6	36
18	11	16	9	2	4
19	12	15	8	4	16
20	13	17	10	3	9
36	14	31	14	0	0
218	105	210	104	1	345

an expected impairment rating of $Y_i + b$. The intercept (a) represents the functional impairment that is expected with a *hypothetical* depression rating of 0. Of course, an HRSD of 0 is not realistic in a clinical trial for subjects meeting criteria for major depressive disorder, but it represents the point along the y-axis where an extrapolated regression line would cross.

The two regression constants are estimated as follows (using the summary data that are presented in Table 14):

$$b = \frac{\sum_{i=1}^{N} xy}{\sum_{i=1}^{N} x^2} = \frac{352}{640} = 0.55$$

$$a = \bar{Y} - b\bar{X} = 14.45 - 0.55 \cdot 21.0 = 2.90$$

Thus, the regression equation is:

$$\hat{Y} = a + bX = 2.90 + 0.55X$$

This indicates that a one-unit increase on the HRSD is associated with a 0.55 unit increase on the Sheehan Disability Scale. A regression line can be graphed by plotting two paired coordinates, $(0,a)$ and $(\bar{X}, \bar{Y})$, and drawing a line between the two points. Applying this to the data from Table 14, the regression line might be graphed by plotting: (0,2.9) and (21,14.45). However, it is inappropriate to extrapolate beyond the range of the sample data. This is because the relation between X and Y might look entirely different for values beyond the range of the data. In the example, the association between functional impairment and depression might be very different for those with minimal depressive symptomatology than for those meeting criteria for major depressive disorder.

In lieu of extending the regression line beyond the range of the sample data, consider the minimum and maximum HRSD (X_i) ratings. In this sample, the HRSD ratings range from 12 to 29. The corresponding predicted functional impairment (i.e., $\hat{Y}_i$) for the lowest and highest HRSD ratings in this sample are estimated by substituting the respective HRSD values in the regression equation:

$$Y = 2.90 + 0.55X = 2.90 + 0.55(12) = 9.50$$

$$Y = 2.90 + 0.55X = 2.90 + 0.55(29) = 18.85$$

Consequently, the regression line, which is presented in Figure 16, will go from (12,9.50) for the least severely ill to (29,18.85) for the most severely ill. Note that the regression line passes through the intersection of the X and Y means, $(\bar{X}, \bar{Y})$, which in this case is (21,14.45).

Recall that the proportion of variance in functional impairment that is explained by depression was presented above in the discussion of the correlation coefficient as: $R^2 = r^2 = 0.648^2 = 0.420$ These are the same data and thus the same value of R^2 applies. As with correlational analyses, R^2 is a measure of the magnitude of the association between Y_i and X_i in simple linear regression. One of the descriptive statistics that was discussed earlier in this chapter is a measure of variability called the sum of squared deviations, in this case, deviations from the Y-mean:

$$\sum y_i^2 = \sum_{i=1}^{N} \left(Y_i - \bar{Y}\right)^2$$

In the context of a regression analysis, this quantity can be partitioned into two components:

$$\sum y_i^2 = \sum \left(\hat{Y}_i - \bar{Y}\right) + \sum \left(Y_i - \hat{Y}_i\right)$$

or

$$\sum y_i^2 = SS_{reg} + SS_{res}$$

The former of the two components, the *sum of squares regression*, or SS_{reg}, represents the sum of squares in Y that is accounted for by X. If one were attempting to guess the level of impairment (Y_i), SS_{reg} can be thought of as the improvement over guessing the mean impairment ($\bar{Y}$) for each subject, and instead using the information known from the sample data about the $X_i - Y_i$ relation. SS_{reg} is estimated as follows (using the summary data from the total row in Table 14):

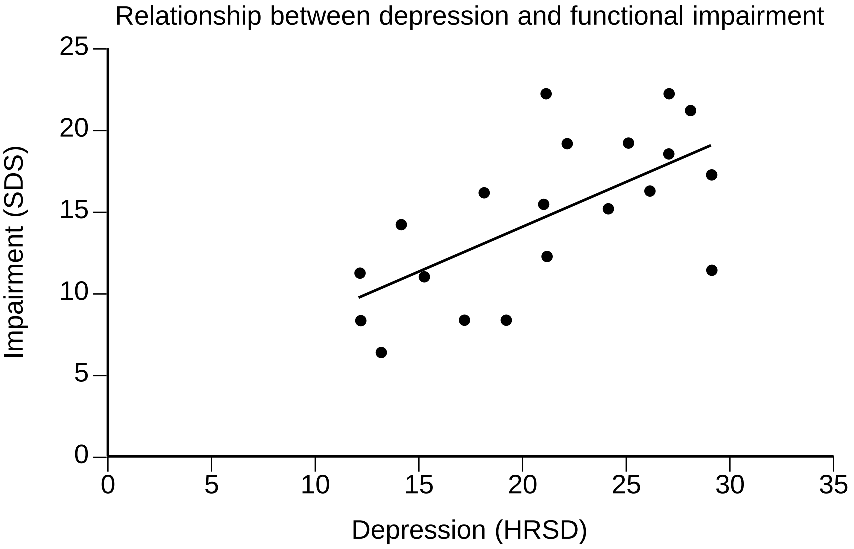

Figure 16 Relationship between depression and functional impairment.

$$SS_{reg} = \sum\left(\hat{Y} - \bar{Y}\right)^2 = \frac{\left(\sum xy\right)^2}{\sum x^2}$$
$$= \frac{352.00^2}{640.0} = 193.6$$

The sum of squares residual (SS_{res}) is the latter component of $\sum y^2$ and represents the sum of squared deviations of Y that is not accounted for by the $X_i - Y_i$ relation:

$$SS_{res} = \sum\left(Y_i - \hat{Y}\right)^2 = \sum y^2 - SS_{reg}$$
$$= 460.95 - 193.6 = 267.35$$

$R^2_{Y\cdot X}$ is the quantity that represents the magnitude of the association between Y and X. It represents the proportion of variance in Y that is accounted for by X:

$$R^2_{Y\cdot X} = \frac{SS_{reg}}{SS_{reg} + SS_{res}} = \frac{193.6}{193.6 + 267.35}$$
$$= 0.42$$

Being a proportion, $R^2_{Y\cdot X}$ can range from 0 to 1; $0 \leqslant R^2_{Y\cdot X} \leqslant 1$. $R^2_{Y\cdot X}$ can also be estimated as follows:

$$R^2_{Y\cdot X} = \frac{\left(\sum xy\right)^2}{\sum x^2} \cdot \frac{1}{\sum y^2} = \frac{352^2}{640} \cdot \frac{1}{460.95}$$
$$= 0.42$$

The first component is the numerator of the prior equation (SS_{reg}) and the second component is the denominator (SS_{res}) of that equation. Presented as one ratio, using the data from Table 14:

$$R^2_{Y\cdot X} = \frac{\left(\sum xy\right)^2}{\sum x^2 \sum y^2} = \frac{352^2}{640 \cdot 460.95} = 0.420$$

which is the square of the correlation between Y and X: $R^2_{Y\cdot X} = r^2_{YX} = 0.648^2 = 0.420$

Thus 42% of the variance in Y is accounted for by X. Although this seems to be a substantial proportion of variance, a statistical test is used to determine whether this is more than might be expected by chance. The null hypothesis, $H_0: \rho^2 = 0$, is tested with an F-test:

$$F = \frac{R^2/k}{(1 - R^2)/(N - k - 1)}$$

where k is equal to the number of independent variables, $k = 1$ in this case:

$$F = \frac{R^2/k}{(1 - R^2)/(N - k - 1)}$$
$$= \frac{.402/1}{(1 - .420)/(20 - 1 - 1)} = 13.034$$

The degrees of freedom for the F-test are k and $(N-k-1)$, or with these data, 1 and 18. The corresponding critical F, $F_{(1,18;\alpha = .05)} = 4.41$. The null hypothesis is rejected because 13.034 > 4.41. In other words, the amount of variance in functional impairment that is explained by depression is statistically significant.

The statistical significance of the regression coefficient b can also be tested using the null hypothesis as $H_0: B = 0$. Consider that if the null hypothesis is not rejected, the regression coefficient could not be considered to be different than zero. Then if $b = 0$, the X-term would fall out of the regression equation, and $\hat{Y}$

would not be a function of X. The statistical significance of the regression coefficient b is tested with a t-ratio, which is equal to the regression coefficient divided by its standard error:

$$t = \frac{b}{s_b}$$

where the standard error of the regression coefficient s_b is estimated as:

$$s_b = \frac{\sqrt{SS_{res}/N - k - 1}}{\sqrt{\sum_{i=1}^{N} x^2}}$$

Notice that since s_b is in the denominator of the t-ratio, a larger value of s_b reduces the value of t. Holding other aspects of the analysis constant, if SS_{res} is large, which can result from a small $X-Y$ relation, then s_b will be large, and t will be small. In contrast, with a larger sample size (N), s_b will be smaller and, as a consequence, t will be larger.

$$SS_{res} = \sum_{i=1}^{N} \left(Y_i - \hat{Y}\right) \sum y^2$$

This quantity incorporates the differences between the observed (Y_i) and predicted ($\hat{Y}_i$) values of Y. In lieu of calculating each of the predicted values, SS_{res} can be calculated using quantities that have been calculated above:

$$SS_{res} = \left(1 - R^2_{Y \cdot X}\right) \sum y^2$$
$$= (1 - .420) \cdot 460.95 = 267.351$$

The standard error of the regression coefficient is given as: s_b

$$s_b = \frac{\sqrt{SS_{res}/N - k - 1}}{\sqrt{\sum_{i=1}^{N} x^2}}$$
$$= \frac{\sqrt{267.351/(20 - 1 - 1)}}{\sqrt{640}} = .152$$

and the t-ratio as:

$$t = \frac{b}{s_b} = \frac{0.55}{0.152} = 3.61$$

In a simple linear regression analysis there is one independent variable. Thus the tests of significance of $R^2_{Y \cdot X}$ and b are synonymous. In fact, the square root of F is equal to t: $\sqrt{13.034} = 3.61$

The assumptions of simple linear regression analysis include:

(i) independence across observations (i.e., subjects);

(ii) the independent variable is fixed;

(iii) the error term (e) is not correlated with the independent variable (X);

(iv) the variance of the error terms is constant across all values of X. This is referred to as homoscedasticity.

The hypothesis testing steps for a simple linear regression analysis are as follows:

(i) State research question. Is there a linear relationship between depression and impairment?

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) Hypotheses about the regression coefficient (β):

$H_0 : \rho_{XY} = 0$
$H_A : \rho_{XY} \neq 0$

(b) Hypotheses about the population R^2 (i.e., ρ^2_{XY}):

$H_0 : \rho^2_{XY} = 0$
$H_A : \rho^2_{XY} \neq 0$

(iii) Choose the t-ratio to evaluate the hypotheses about the regression coefficient (β). Use an F-test to test hypotheses about R^2.

(iv) The critical value for the t-ratio with two-tailed $\alpha = 0.05$ and df = 18 is 2.101. If $t_{\text{observed}} > t_{\text{critical}}$, reject $H_0 : \beta_{XY} = 0$. The critical value for the F-test with $\alpha = 0.05$ and df = 1,18 is 4.41. If $F_{\text{observed}} > F_{\text{critical}}$, reject $H_0 : \rho^2_{XY} = 0$.

(v) Data regarding depression and impairment are given in Table 14.

(vi) Calculations were described above.

(vii) Decision regarding H_0 about (β). Observed $t >$ critical t, thus reject H_0 (i.e., $3.61 > 2.101$). Decision regarding H_0 about R^2. Observed $F >$ critical F (i.e., $13.064 > 4.41$), thus reject H_0.

(vii) Conclusion. Based on data from this sample, we conclude that there is a statistically significant linear relationship between depression and impairment.

Linear regression is a useful statistical procedure for examining a bivariate relation. Unlike a correlational analysis in which $r_{yx} = r_{xy}$, linear regression is *not* a symmetric procedure. That is, the regression of Y_i on X_i will not result in the same regression constants (a and b) as the regression of Y_i on Y_i.

3.12.4.4.5 Multiple linear regression analysis

A *simple* linear regression analysis involves the regression of a dependent variable on one independent variable. *Multiple* linear regression analysis extends the statistical model such that one dependent variable is regressed on multiple independent variables. Multiple linear regression analysis is a general statistical model that can evaluate both dimensional and categorical independent variables. In fact it can test main effects and interactions of the ANOVA model and can be used to control for variables (i.e., covariates) if certain assumptions are fulfilled (see Pedhazur, 1982, Chap. 12).

Pedhazur (1982) distinguishes between the use of regression for prediction and explanation. The former has to do with estimating the dependent variable given a value of the independent variable (i.e., Y_i given X_i), whereas the latter focuses on the proportion of variance in the dependent variable that is explained by the independent variables (R^2). Although this chapter will not discuss multiple linear regression analysis in detail, several comprehensive examinations of multiple linear regression analysis are available (Aiken & West, 1991; Cohen & Cohen, 1983; Cook & Weisberg, 1982; Neter, Wasserman, & Kutner, 1989; Pedhazur, 1982; Pedhazur & Schmelkin, 1991).

3.12.4.5 Between-subject Designs: Categorical Dependent Variables

The statistical procedures that have been discussed until this point in the chapter are appropriate for continuous or ordinal dependent variables. Nevertheless, it is not unusual for the dependent variable to be categorical. There are a multitude of examples: pass or fail, sick or well, and live or die. There are many statistical procedures for categorical data and comprehensive texts devoted exclusively to categorical data analysis (see for example Agresti, 1996; Bishop, Feinberg, & Holland, 1975; Fleiss, 1981).

Consider the data from the hypothetical clinical trial that have been used throughout this chapter (originally presented in Tables 3 and 5). The HRSD is a continuous dependent variable that could be dichotomized such that the subjects with an HRSD rating of 14 or less are classified as "responders" and all other subjects are classified as "nonresponders." (For readers familiar with the HRSD, this is a rather crude and quite unconventional threshold, used only as an example for data analysis and not for the study of psychopathology.) Both the independent variable (treatment CBT vs. IPT) and the dependent variable (response: yes vs. no) are categorical variables. Although there is some literature discouraging categorization of continuous measures because of the loss of precision and statistical power, in the clinical setting decisions often must be dichotomous.

Table 16 Treatment response status of subjects in CBT and IPT groups

	Nonresponse	*Response*	*Total*
CBT	16 (a)	4 (b)	20
[row %]	[80%]	[20%]	[100%]
{column %}	{57.1%}	{33.3%}	{50%}
IPT	12 (c)	8 (d)	20
[row %]	[60%]	[40%]	[100%]
{column %}	{42.9%}	{66.7%}	{50%}
Total	28	12	40
[row %]	[70%]	[30%]	[100%]
{column %}	{100%}	{100%}	{100%}

3.12.4.5.1 *Chi-square test*

The chi-square (χ^2) test is generally used to compare rates or proportions across groups (Fleiss, 1981). In the example presented in Table 16, the χ^2 test is used to compare the response rates, and determine if rates as diverse as 20% and 40% can be expected by chance. This format of data display is referred to as a *contingency table*. Initially, notice that the IPT group had twice the response rate as the CBT group (40% vs. 20%). Also note the degree to which the rate for each group differs from that of the marginal (30%), which is presented in the margins of Table 16, and represents the response rate of the sample as a whole ($N = 40$).

The null hypothesis is that the population rates do not differ, $H_A: \pi_1 = \pi_2$. That hypothesis is tested by comparing the *observed* cell frequencies with those *expected* if treatment and response were independent. It is tested in the following manner:

$$\chi^2 = n_{..} \sum_{i=1}^{2} \sum_{j=1}^{2} \frac{\left(\left|p_{ij} - p_i p_j\right| - 1/(2n_{..})\right)^2}{p_{i.} p_{.j}}$$

where p_{ij} is the proportion of the entire sample that is in row i and column j (i.e., $cell_{ij}$). Note that a dot (.) in the subscript represents a dimension (row or column) that is ignored. For example, the marginal value $p_{i.}$ represents the proportion of subjects in row i and $p_{.j}$ represents the proportion of subjects in column j. The product of those marginal proportions is the proportion of subjects that would be expected in the cell if the row and column variables were independent of each other. This product is referred to as the *expected value*. The χ^2 test essentially compares the *observed* and *expected* values. Applied to the data from Table 16:

$$\chi^2 = \frac{(|.10 - .50\cdot .70| - 1/(2\cdot 40))^2}{.50\cdot .70} + \frac{(|.40 - .50\cdot .30| - 1/(2\cdot 40))^2}{.50\cdot .30} + \frac{(|.3 - .50\cdot .70| - 1/(2\cdot 40))^2}{.50\cdot .70} + \frac{(|20 - .50\cdot .30| - 1/(2\cdot 40))^2}{.50\cdot .30} = 1.07$$

Another algorithm for a *fourfold table* (i.e., a two by two contingency table) is somewhat simpler, using cell and marginal frequencies, but no proportions:

$$\chi^2 = \frac{n..(|n_{11}n_{22} - n_{12}n_{21}| - \frac{1}{2}n_{..})^2}{n_{1.}n_{2.}n_{.1}n_{.2}}$$

With the data presented in Table 16:

$$\chi^2 = \frac{40(|16\cdot 8 - 4\cdot 12| - \frac{1}{2}40)^2}{20\cdot 20\cdot 28\cdot 12} = 1.07$$

Assumptions of the χ^2 test include:

(i) The samples are independent of each other.

(ii) The subjects within each group are independent of each other.

(iii) No subject can be classified in more than one category.

(iv) No cell has an expected value less than five.

The hypothesis testing steps for the χ^2 test are as follows:

(i) State research question. Do CBT and IPT have similar effects for the treatment of patients with depression?

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) $H_0: \pi_1 = \pi_2$

(b) $H_A: \pi_1 \neq \pi_2$

(iii) If the assumptions are met, use the χ^2 test to evaluate the hypotheses.

(iv) The critical value for the χ^2 test with two-tailed $\alpha = 0.05$ and df = 1 is 3.84. (Note that df is equal to the product of # rows and # columns.) If $\chi^2_{\text{observed}} > \chi^2_{\text{critical}}$, reject H_0.

(v) Data are displayed in Table 16.

(vi) Calculations were described above.

(vii) Decision regarding H_0: $\chi^2_{\text{observed}} < \chi^2_{\text{critical}}$ (i.e., $1.07 < 3.84$), thus do not reject H_0.

(viii) Conclusion. In this sample of patients with major depressive disorder, those who were treated with IPT did not have different response rates than those who were treated with CBT.

The null hypothesis is not rejected because the difference in response rates across treatment groups (20% vs. 40%) is not more than is expected by chance. The chi square test can also be used for two-way contingency tables that have more than two rows and two columns.

3.12.4.5.2 Fisher's Exact test

When at least one expected frequency in a fourfold table is less than five, the Fisher's Exact test is more appropriate than the χ^2 test. The test assesses the probability of the cell frequencies, given the marginal frequencies. Stated differently, given the respective sample sizes and the response rates of the sample as a whole, the Fisher's Exact test evaluates the probability of the four cell frequencies. The algorithm, which is based on the hypergeometric probability distribution, is:

$$p = \frac{n_{1.}!n_{2.}!n_{.1}!n_{.2}!}{n_{..}!n_{11}!n_{12}!n_{21}!n_{22}!}$$

Where "*n*-factorial" ($n!$),

$$n! = n\cdot(n-1)\cdot(n-2)\cdot\ldots\cdot 1$$

and, by definition, $0! = 1$.

The algorithm for p calculates the probability of getting precisely the observed configuration of frequencies. There were no expected frequencies that were less than five in Table 16. For that reason, the data in Panel A of Table 17 will be used to illustrate the calculations involved in a Fisher's Exact test. These data, which will be referred to as the *observed* data, come from a *hypothetical pilot* study comparing electroconvulsive therapy (ECT) and psychodynamic psychotherapy (PP) for the treatment of dysthymia. The response rates were 93.33% for ECT and 85.0% for PP.

Applying the above algorithm:

$$p = \frac{15!\cdot 20!\cdot 4!\cdot 31!}{35!\cdot 1!\cdot 14!\cdot 3!\cdot 17} = 0.3266$$

That is, given the observed marginals, about one of every three *random* configurations will be that which is contained in Table 17. Consider that there are only four other configurations of cell frequencies that conform to the marginals of this contingency table, which are also presented in Table 17, Panels B–E. Fisher's Exact test involves calculating the probability of each configuration that conforms to the marginals. Applying the equation that was presented above, the respective probabilities of those tables are presented in the final column of Table 17. (Note that the sum of these four probabilities, and that of the *observed* table, 0.3266, is 1.00. That is, the probability of *any* of the possible outcomes is 1.00.)

For the Fisher's Exact test, one determines which of the configurations have a probability that is less than or equal to the probability

Table 17 Treatment by responder status.

	Configuration	*Treatment*	*Nonresponder*	*Responder*	*Total*	*p*
Panel A	#1	ECT	1	14	15	0.3266
		PP	3	17	20	
		Total	4	31	35	
Panel B	#2	ECT	0	15	15	0.0925
		PP	4	16	20	
		Total	4	31	35	
Panel C	#3	ECT	2	13	15	0.3810
		PP	2	18	20	
		Total	4	31	35	
Panel D	#4	ECT	3	12	15	0.1738
		PP	1	19	20	
		Total	4	31	35	
Panel E	#5	ECT	4	11	15	0.0261
		PP	0	20	20	
		Total	4	31	35	

associated with the *observed* contingency table, configuration #1. In this case, the probabilities of configurations #2 ($p = 0.0925$), #4 ($p = 0.1738$), and #5 ($p = 0.0261$) are all less than the observed configuration #1 ($p = 0.3266$). These probabilities, and that of the observed, are summed and compared to the alpha level:

$$p^* = 0.0925 + 0.1738 + 0.0261 + 0.3266 = 0.6190$$

Assumptions of the Fisher's Exact test are as follows:

(i) The data are in a contingency table with two rows and two columns.

(ii) The samples are independent of each other.

(iii) The subjects within each group are independent of each other.

(iv) No subject can be classified in more than one category.

(v) The row and column totals are given. They are not random.

The hypothesis testing steps for the Fisher's Exact test are as follows:

(i) State research question. Do ECT and PP have similar effects on *response*?

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) $H_0: \pi_1 = \pi_2$

(b) $H_A: \pi_1 \neq \pi_2$

(iii) If assumptions are fulfilled, use Fisher's Exact test to evaluate the hypotheses.

(iv) The critical value for the Fisher's Exact test with two-tailed $\alpha = 0.05$ is 0.05. If $p^* \leqslant 0.05$, reject H_0.

(v) Data are displayed in Table 17.

(vi) Calculations were described above.

(vii) Decision regarding H_0: $p^*_{\text{observed}} > p_{\text{critical}}$ (i.e., $0.619 > 0.05$), thus do not reject H_0.

(viii) Conclusion. Dysthymic subjects treated with ECT and PP do not have differential response rates.

There is a growing body of literature on the use of *exact tests*, such as that just described, in other contexts (e.g., Agresti, 1992; Mehta & Patel, 1997). These procedures are based on minimal distributional assumptions. As a consequence they can be applied in situations when the use of other procedures is more tenuous, particularly with small data sets. Because exact procedures are often computationally extensive, their use was rare until software that implemented the exact algorithms were available. StatXact software (Mehta & Patel, 1997) is designed to conduct exact tests for a wide variety of types of data. It is available as a stand-alone package and also as an add-on module with statistical software such as SPSS and SAS.

3.12.4.5.3 Logistic regression

Logistic regression analysis is used to examine the association of (categorical or continuous) independent variable(s) with one *dichotomous* dependent variable. This is in contrast to *linear* regression analysis in which the dependent variable is a continuous variable. The discussion of logistic regression in this chapter is brief. Hosmer and Lemeshow (1989) provide a comprehensive introduction to logistic regression analysis.

Consider an example in which logistic regression could be used to examine the research question, “Is a history of suicide attempts associated with the risk of a subsequent (i.e., prospectively observed) attempt?” The logistic regression model compares the odds of a prospective attempt in those with and without prior attempts. The ratio of those odds is called the *odds ratio*. A logistic regression does not analyze the odds, but a natural logarithmic transformation of the odds, the log odds. Although the calculations are more complicated when there are multiple independent variables, computer programs can be used to perform the analyses. However, because of the logarithmic transformation of the odds ratio, the interpretation of results from the computer output is not necessarily straightforward. Interpretation requires a transformation back to the original scale by taking the inverse of the natural log of the regression coefficient, which is called *exponentiation*. The exponentiated regression coefficient represents the strength of the association of the independent variable with the outcome. More specifically, it represents the increase (or decrease) in risk of the outcome that is associated with the independent variable. The exponentiated regression coefficient represents the difference in risk of the outcome (e.g., suicide attempt) for two subjects who differ by one point on the independent variable. In this case, that is the difference between those with and without history of attempts (i.e., when history of attempts is coded: 0 = no and 1 = yes).

The logistic regression model can be extended to include several independent variables (i.e., hypothesized risk factors). For instance, are history of attempts, severity of depression, and employment status risk factors for suicidal behavior, controlling for diagnosis, age, and gender? Each odds ratio from such a model represents the change in risk of the outcome (i.e., a suicide attempt) that is associated with the independent variable, controlling for the other independent variables.

3.12.4.5.4 Survival analysis

In a study such as the example used above, the probability of the event is somewhat constrained by the follow-up time of the study. That is, the number of subjects with a suicide attempt will very likely be much smaller in a six-week study than in a six-year study. Survival analysis is a statistical technique that is used to examine the risk of an event *over time*. As with logistic regression analysis, this technique is appropriate for a dichotomous dependent variable. For example, survival analyses can be used to examine the risk of a suicide attempt over the course of a follow-up study. The survival model incorporates the differential risk period of the subjects. For that reason, it makes use of the available data in a follow-up study.

For example, in a 15-year follow-up study of subjects with affective disorders, some of the subjects will be followed for the entire study. Yet others will be followed for as short as a few weeks and others for several years, but not the duration of the entire 15-year study. The Kaplan–Meier product limit estimate (Kaplan & Meier, 1958) is used to estimate the proportion of subjects who have not had a postbaseline suicide attempt (i.e., the proportion *surviving* without a suicide attempt). Patients who do not attempt suicide by the end of follow-up, or who drop out of the follow-up study, are classified as *censored*. The Kaplan-Meier (1958) estimate is calculated as the probability of the event up to a given point in the follow-up. In this example, say that there are monthly assessments in which the investigators ask about psychopathology, suicide attempts, and treatment during the preceding month. The researcher could estimate the proportion of subjects who remained *suicide-free* after one month, two months, and so on to the end of follow-up.

There are several survival analytic procedures. For instance, the cumulative probability of an event (i.e., a suicide attempt) can be compared across groups using a logrank test (Peto & Peto, 1972). The survival model can be further extended to incorporate many independent variables that are hypothesized to be associated with risk of the event using a Cox proportional hazards regression model (Cox, 1972). There are several comprehensive texts on survival analytic techniques (e.g., Collett, 1994; Kalbfleisch & Prentice, 1980; Lawless, 1982; Lee, 1980; Parmar & Machin, 1995).

3.12.4.6 Within-subject Designs: Dimensional and Ordinal Dependent Variables

Subjects can serve as their own controls by being successively exposed to each treatment condition. The major advantage is that a design such as this reduces the between-subject variability that is inherent in a between-subjects design. As a consequence, a smaller number of subjects is needed in such a study. However, this design is inappropriate for many types of experimental intervention. For instance, the approach cannot be used in most studies of learning, unless it is feasible to get subjects to *unlearn* a task that has been mastered. The same holds true for acute treatment of psychopathology. Once a subject is well, the efficacy of subsequent treatments cannot be evaluated.

3.12.4.6.1 *Paired* t*-test*

The paired *t*-test is used for a within-subject comparison of dimensional dependent variables. For example, in a one-group design, the pretreatment HRSD scores could be compared with the post-treatment HRSD scores. (Note that there are many reasons that a multigroup design is preferable, but that is beyond the scope of this presentation. See Campbell & Stanley, 1963, for a comprehensive discussion of this.) The null hypothesis is $H_0: \mu_{\text{pre}} = \mu_{\text{post}}$, whereas the alternative hypothesis is $H_A: \mu_{\text{pre}} \neq \mu_{\text{post}}$. Stated differently, the data that are examined are the paired differences ($d_i = X_i - Y_i$) between preatment (X_i) and post-treatment (Y_i) for each subject. A mean difference ($\bar{d}$) and standard deviation of *differences* (s_d) are calculated.

For illustration, Table 18 presents HRSD scores for a group of 20 subjects before and after CBT treatment of depression. (At this point, focus only on the first three columns of Table 18.) Prior to treatment, the mean HRSD rating was 21.0 (sd = 5.8). After treatment, the mean HRSD rating was reduced to 15.95 (sd = 5.8). The paired *t*-test, which can generally be thought of as a test of whether the mean *difference* is equal to zero, is calculated as follows:

$$t = \bar{d}/s_{\bar{d}} \quad \text{where}$$

$$s_{\bar{d}} = \sqrt{\frac{s_d^2}{n}}$$

and s_d^2 is the variance of the *differences* (i.e., the square of the standard deviation of the *differences*):

$$s_d^2 = 5.46^2 = 29.84$$

$$s_{\bar{d}} = \sqrt{\frac{s_d^2}{n}} = \sqrt{\frac{29.84}{20}} = 1.22$$

$$t = \frac{\bar{d}}{s_{\bar{d}}} = \frac{5.10}{1.22} = 4.13$$

In a paired *t*-test, it is assumed that

(i) the data consist of correlated pairs of observations (i.e., paired data);

(ii) the subjects are randomly sampled;

(iii) the differences between each pair of observations are from a normally distributed population of differences.

The hypothesis testing steps for the paired *t*-test are as follows:

(i) State research question. Is there a difference in depression severity from pre- to post-CBT treatment?

(ii) State two mutually exclusive and exhaustive hypotheses:

(a) $H_0: \mu_d = 0$

(b) $H_A: \mu_d \neq 0$

(iii) If assumptions are met, use the paired *t*-test.

(vi) The critical value for the paired *t*-test with a two-tailed $\alpha = 0.05$ and $df = 19$, $t_{\text{critical}} = 2.093$ (Note that for a paired *t*-test, *df* is equal to one less than the number of pairs.) If $t_{\text{observed}} > t_{\text{critical}}$, reject H_0.

(v) Data are displayed in Table 18.

(vi) Calculations were described above.

(vii) Decision regarding H_0: $t_{\text{observed}} > t_{\text{critical}}$ (i.e., $4.13 > 2.093$), thus reject H_0.

(viii) Conclusion. There is a statistically significant reduction in severity of depression, as measured by the HRSD, from pre- to post-CBT treatment.

3.12.4.6.2 *Wilcoxon signed-rank test*

The Wilcoxon signed-rank test is used to test differences of paired data without the normal distribution assumption of the differences that is required for the paired *t*-test. The procedure is as follows. First, the difference between each pair of data is calculated. The differences are then ranked. Next, the ranks are assigned the sign ($\pm$) of the corresponding difference. Then two sums are computed: the sum of the positive signed ranks (T_+) and the sum of the absolute values of the negative signed ranks (T_-). (The differences of zero are ignored in these calculations.) Note that the sum of the totals should be: $T_+ + T_- = n(n+1)/2$, where *n* is the number of nonzero differences. If H_0 were true, one would expect about half of the differences to be positive and about half of the differences to be negative. If so, the sum of positive ranks would be approximately equal to the sum of the negative ranks: $T_+ \approx T_- \approx 1/2 \cdot n(n+1)/2$. The test statistic ($W_{\text{obs}}$) is used to examine this. W_{obs} is equal to the smaller of the two signed rank totals.

For example, see Table 18 which displays the pre- and post-HRSD scores and the difference scores. The median pretreatment rating (21.0) and the median post-treatment rating (15.0) appear to be quite different. The Wilcoxon Rank Sum test examines the magnitude of the difference. Separate columns display the ranks of the positive differences and the ranks of the absolute values of the

Table 18 HRSD scores: pre-(X) and post-(Y) CBT treatment ($N = 20$).

	X	*Y*	*Difference*	*Ranked |Difference|*	*Signed rank*	*Positive ranks*	*Negative ranks*
	12	11	1	5	5	5	
	12	4	8	15.5	15.5	15.5	
	13	15	−2	3	−3		3
	14	8	6	11	11	11	
	15	9	6	11	11	11	
	17	8	9	17	17	17	
	18	11	7	14	14	14	
	19	13	6	11	11	11	
	21	5	16	20	20	20	
	21	22	−1	4	−4		4
	21	28	−7	1	−1		1
	22	25	−3	2	−2		2
	24	21	3	6	6	6	
	25	15	10	18	18	18	
	26	22	4	7	7	7	
	27	22	5	8	8	8	
	27	14	13	19	19	19	
	28	22	6	11	11	11	
	29	23	6	11	11	11	
	29	21	8	15.5	15.5	15.5	
Total	420.00	319.00	101.00	210.00	190.00	200.00	10.00
Mean	21.00	15.95	5.05				
sd	5.80	7.16	5.46				

$d = X - Y$.

negative differences. The sums of those columns are:

$$T_+ = 200$$

$$T_+ = 10$$

$$W_{\text{observed}} = T_- = 10$$

Check the calculations the sum of the positive signed ranks and absolute values of the negative signed ranks:

$$T_+ + T_- = \frac{n(n+1)}{2}$$

$$T_+ + T_- = 200 + 10 = 210$$

$$\text{and} \quad \frac{\text{n(n+1)}}{2} = \frac{20(20+1)}{2} = 210$$

The assumptions of the Wilcoxon Signed Rank Sum test include:

(i) the data consist of correlated observations (i.e., paired data);

(ii) subjects with paired data are randomly and independently sampled;

(iii) The differences are measured on at least an ordinal scale.

The hypothesis testing steps for the Wilcoxon Signed Rank Sum test are as follows:

(i) State research question. Is there a difference in depression severity from pre- to post-CBT treatment?

(ii) State two mutually exclusive and exhaustive hypotheses with regard to location (e.g., median):

(a) $H_0 : \text{Median}_{\text{Time1}} = \text{Median}_{\text{Time2}}$

(b) $H_A : \text{Median}_{\text{Time1}} \neq \text{Median}_{\text{Time2}}$

(iii) If the assumptions are fulfilled, use the Wilcoxon Signed Rank Sum test to evaluate the hypotheses.

(iv) The critical value for the Wilcoxon Signed Rank Sum test, with two-tailed $\alpha = 0.05$ and $N = 20$, is $W_{\text{observed}} < W_{\text{critical}}$, reject H_0.

(v) Data are displayed in Table 18.

(vi) Calculations were described above.

(vii) Decision regarding $H_0 : W_{\text{observed}} < W_{\text{critical}}$ (i.e., $22.5 < 52$), thus reject H_0.

(viii) Conclusion. There is a significant reduction in depressive severity from pre- to post-CBT treatment.

3.12.4.6.3 Repeated measures ANOVA

The repeated measures ANOVA is a statistical procedure that can include both *within*-subject and *between*-subject factors. Initially the former will be considered. Most simply, it can be an extension of the paired t-test, used to compare subjects over time. Consider three HRSD assessments during the course of 12 weeks of CBT (e.g., weeks 0, 6, and 12). The null hypothesis is that there is no change in depression over the three assessments: $H_0 : \mu_1 = \mu_2 = \mu_3$. The alternative hypothesis is that the null hypothesis is false. The *F*-test of the repeated measures ANOVA tests whether that difference is more than can be expected by chance. If H_0 is rejected, the source of the difference must be examined more closely in a *post hoc* test. This is discussed in detail elsewhere (e.g., Keppel, 1991; Winer, 1971).

3.12.4.7 Within-subject Designs: Categorical Dependent Variables

The repeated measures design can be extended to include *between*-subject factors as well as *within*-subject factors. Such a design is referred to as a *split plot design*. There are two types of within- and between-subject factors: *fixed* and *random* effects. The specific levels of fixed variables are determined by the experimenter, whereas the levels of a random effect are randomly selected from a larger population of levels. Results of fixed effects cannot be generalized beyond the levels of the factors that are tested. In contrast, results of random effects can be generalized to the population from which the levels were selected. The within-subject factor that was discussed in the repeated measures model above, was a fixed effect. Random effects are discussed in detail elsewhere (e.g., Keppel, 1991; Winer, 1971). An extension of the previous example that includes two independent treatment groups (e.g., IPT vs. CBT) illustrates a design in which a repeated measures ANOVA with both within-subject and between-subject factors would be applied. Treatment would be the between-subjects factor, whereas time would be the within-subjects factor. Subjects are treated with only one modality, but have all levels of the within-subject factor (i.e., assessments at weeks 0, 6, and 12). This ANOVA includes three *F*-tests: the main effect of treatment, the main effect of time, and the interaction of treatment by time.

3.12.4.7.1 McNemar test

The McNemar test is used to examine paired dichotomous data. For example, one might compare the symptomatology pretreatment and post-treatment. Specifically, one might hypothesize that the sleep disturbance is neither developed nor overcome during the course of treatment with IPT for depression as presented in Table 19. The McNemar test is calculated as follows: $\chi^2 = (|b - c| - 1)^2/b + c$. (The algorithm, as presented with the term outside of the absolute value, incorporates a continuity correction in the numerator.) Note that the calculations focus on the *discordant* pairs and ignore the *concordant* pairs. More specifically, the test is a ratio of the squared difference in discordant frequencies relative to the total discordant frequencies. In the example above, the test would detect a disproportionate representation of an emergent sleep disturbance among those who had a change in sleep disturbance. This is illustrated with data in Table 19, where 11 of the 13 (84.5%) with changes in sleep disturbance developed the symptom during the course of treatment: $\chi^2 = (|11 - 2| - 1)^2/(11 + 2) = 4.92$. The McNemar χ^2 of 4.92 exceeds the critical χ_2 with 1 *df*, 3.84, and is thus statistically significant at the 0.05 level.

3.12.5 SUMMARY

There are several components of the analysis one must consider when choosing among statistical procedures. Is there a dependent variable? If so, is it dimensional, ordinal, or categorical? What are the comparisons that will answer the research question? Are there group comparisons? If so, how many groups are being compared? If not, is it bivariate linear relations that are of interest? In addition, the assumptions of the statistical procedures should be carefully considered before the procedure is applied. Figure 17 is a flow chart that is designed to facilitate selection of the appropriate inferential statistical procedure.

Finally, the value of descriptive statistical procedures must not be minimized. They are used not only to summarize data and describe a sample, but also to help a researcher become familiar with the data. The initial examination of descriptive statistics provides information that is useful when choosing among inferential statistical procedures.

In summary, this chapter began by stating that a fundamental motivation in science is to understand individual differences. A variety of

statistical procedures that are used to examine *deviation* and *variability* have been outlined. The decision rules to choose among them has been discussed. Reference citations have been provided for a more comprehensive discussion of each technique. In closing, the reader is encouraged to consider not only the test statistic and corresponding *statistical significance* of research results, but also focus on the *clinical meaningfulness* of the findings. If a result cannot be replicated because it is trivial or if a finding has no practical value, it will serve no useful scientific or clinical purpose.

3.13.1 INTRODUCTION

Many psychological investigations involve the collection of multivariate data, a term used when more than a single variable value is observed on each subject in a study. Table 1, for example, shows a set of data giving the examination scores obtained in four subjects by 15 students. For many such data sets the question of most interest is how the variables are related, and the first step in answering this question usually involves the calculation of the covariance or more commonly the correlation between each pair of variables (Table 2).

The techniques discussed in this chapter are aimed primarily at explaining and describing as concisely as possible the relationships between the variables in a set of multivariate data. Some of the methods are most applicable when the investigator has only limited expectation of what patterns to expect, and wishes to explore the covariance or correlation matrix in an effort to uncover hopefully some psychologically meaningful structure. Other methods are designed to test specific

theories or hypotheses as to why the variables have their observed relationships. Both approaches rely heavily on the concept of a latent variable, a topic discussed in the next section.

3.13.2 LATENT VARIABLES, OR, HOW LONG IS A PIECE OF STRING?

Table 3 shows the lengths of 15 pieces of string as measured by a ruler (R) and as estimated (guessed) by three different people (G, B, and D). Corresponding to each piece of string is a true but unknown length. The four observed measurements all give the true length plus some amount of measurement error, although R is likely to be considerably more accurate than the others. The four measurements are said to be fallible indicators of length.

Fascinating though the data in Table 3 may be (at least to the author), many readers of this article may quite reasonably ask what they have to do with psychology in general, and factor analysis in particular? To answer such questions consider again the data shown in Table 1, consisting of the examination scores of 15 individuals in four subjects. Analogous to the true string length of each of the 15 observations in Table 3, each individual in Table 1 might be assumed to have a particular, but unknown, level of cognitive ability (which some bolder psychologists might label "intelligence"), of which the four observed examinations scores are again fallible indicators.

And so in the data sets in both Tables 1 and 3, it can be assumed that the observed or manifest variables are fallible indicators of an underlying variable that cannot be measured directly—a so-called latent variable. Length is, of course, a far more straightforward latent variable than intelligence and one which most people would find little difficulty in accepting; its direct measurement is prevented simply by measurement error. Many of the latent variables postulated in psychology and related disciplines, however, are often more problematical and even in some cases controversial. Certainly there has been considerable debate about the nature of intelligence. The reason that such variables cannot be measured directly is often more complex than simple measurement error.

The question of how seriously latent variables should be taken in general is discussed in Section 3.13.5 but, as will be seen in later examples, invoking the concept of a latent variable is frequently extremely useful when exploring the relationships between manifest variables. In an exploratory analysis the aim will be to assess whether there is any evidence that the structure in an observed correlation matrix is due to a number of underlying latent variables and, if so, to describe and possibly label these variables.

When testing a specific hypothesis or model for the data, the relationships between the observed and latent variables will be specified *a priori,* and the investigator will be primarily interested in assessing the fit of the suggested model for the observed correlations or covariances. In addition to specifying how observed and latent variables are related, more complex models might also specify relationships between the latent variables themselves; examples are given later.

3.13.3 FACTOR ANALYSIS

Factor analysis is a generic term given to a class of multivariate statistical methods whose primary purpose is data reduction and summarization. In general terms factor analysis

Table 2 Covariances and correlations.

(i) A set of multivariate data is generally represented by a matrix **X** where

$$\mathbf{X}=\begin{bmatrix} x_{11} & x_{12} & \dots & x_{1p} \\ x_{21} & x_{22} & \dots & x_{2p} \\ \vdots & \vdots & \vdots & \vdots \\ x_{n1} & x_{n2} & \dots & x_{np} \end{bmatrix}$$

where n is the number of observations in the data, p is the number of variables, and x_{ij} represents the value of variable j for observation i

(ii) The sample covariance s_{ij} of variables i and j is given by

$$s_{ij} = \frac{1}{n-1} \sum_{k=1}^{n} (x_{ki} - \bar{x}_i)(x_{kj} - \bar{x}_j)$$

where $\bar{x}_i$ and $\bar{x}_j$ are the sample means of the two variables

(iii) A covariance can take any value from $-\infty$ to ∞. A value of zero indicates that there is no association (strictly, no linear association) between the variables. A positive value occurs when, as one of the variables increases in value then, on average, so does the other. A negative covariance indicates that as one variable increases, the other decreases, and vice versa

(iv) The sample covariance matrix is a matrix with the variances of each variable on the main diagonal and the covariances of each pair of variables as off-diagonal elements

(v) The sample correlation coefficient, r_{ij} between variables i and j is given by

$$r_{ij} = \frac{s_{ij}}{(s_{ii}s_{jj})^{\frac{1}{2}}}$$

where s_{ii} and s_{jj} are used to denote the variances of the two variables

(vi) A correlation takes values between -1 and 1, with the two extremes indicating that the two variables are perfectly linearly related

(vii) The sample correlation matrix is

$$\mathbf{R}=\begin{bmatrix} 1 & r_{12} & \dots & r_{1p} \\ r_{21} & 1 & \dots & r_{2p} \\ \vdots & \vdots & \vdots & \vdots \\ r_{p1} & r_{p2} & \dots & 1 \end{bmatrix}$$

techniques address themselves to the problem of analyzing the interrelationships amongst a possibly large set of observed variables and explaining these relationships in terms of a (hopefully) small number of underlying latent variables. By using factor analysis, the investigator should be able to identify the separate dimensions being measured by the manifest variables. When used in an exploratory mode, factor analysis methods place no constraints on the possible relationships between observed and latent variables. When used in a confirmatory manner, however, these relationships will be constrained in particular ways specified by the hypothesized model. The next section deals with exploratory factor analysis and Section 3.13.3.2 with confirmatory factor analysis.

3.13.3.1 Exploratory Factor Analysis

The mathematical details of the factor analysis model are listed in Table 4, and the essential features of the technique are now demonstrated by considering an application.

3.13.3.1.1 Statements about pain

This illustration is based on a subset of the data reported in Skevington (1990). The study was concerned with beliefs about controlling pain and 123 individuals suffering from severe pain were presented with nine statements about pain. Each statement was scored on a scale from 1 to 6, ranging from disagreement to agreement. The nine statements and the observed correlations between them are shown in Table 5. One of the aims of the study was to ascertain whether the responses reflected the existence of subscales or groups of attitudes.

In an attempt to identify the latent variables that might account for the observed pattern of correlations between the pain statements, a particular form of factor analysis, maximum likelihood factor analysis was applied (described by Everitt & Dunn, 1991). The results from a factor analysis consist of the estimated regression coefficients of each observed variable on each latent variable (also known in this context as common factors). When the factor analysis has been carried out on the observed correlation matrix rather than the covariance matrix, the estimated regression coefficients are simply the correlations between each manifest variable and each latent variable. (In an exploratory factor analysis the choice of covariance or correlation matrix is not critical since there is a simple relationship between the solutions derived from each.) Table 6 shows these estimated correlations for both the two- and three-factor solutions. (Methods for deciding on the appropriate number of common factors are discussed later.)

How are the results given by a factor analysis interpreted? First, the estimated correlations (more commonly known as factor loadings) can be used to identify and perhaps name the underlying latent variables, although this is often more straightforward after the process of rotation, which is discussed in Section 3.13.3.1.3. But for now, examining the unrotated results in Table 6 it is seen that for both solutions the second factor is positively correlated, to a greater or lesser extent, with all nine statements. It would not require a great leap of imagination to suggest that this factor might be labeled "general pain level." The first factor is negatively correlated with statements taking personal responsibility for one's pain and positively correlated with statements in which the control of, and reasons for, pain are attributed elsewhere. Factors with a mixture of positive and negative loadings (often referred to as bipolar factors), usually become easier to understand after rotation and so further interpretation of the results is left until Section 3.13.3.1.3.

Apart from the factor loadings, a number of other quantities which need explanation are given in Table 6. First, the sum of squares of the factor loadings of a particular observed variable gives what is known as the communality of that variable, that is, the variance shared with the other manifest variables via their relationships with the common factors. Subtracting the communality of a variable

Table 4 The factor analysis model.

(i) In general terms factor analysis is concerned with whether the covariance, or correlations between a set of observed variables, $x_1, x_2, \dots, x_p$ can be explained in terms of a smaller number of unobservable latent variables (common factors), $f_1, f_2, \dots f_k$ where $k < p$ (hopefully k, the number of common factors, will be much less than the number of original variables p)

(ii) The factor analysis model is essentially a regression-type model in which the observed variables are regressed on the assumed common factors. In mathematical terms the factor analysis model can be written as

$$
\begin{aligned}
x_1 &= \lambda_{11}f_1 + \lambda_{12}f_2 + \dots + \lambda_{ik}f_k + e_1 \\
x_2 &= \lambda_{21}f_1 + \lambda_{22}f_2 + \dots + \lambda_{2k}f_k + e_2 \\
&\cdot \\
&\cdot \\
&\cdot \\
x_p &= \lambda_{p1}f_1 + \lambda_{p2}f_2 + \dots + \lambda_{pk}f_k + e_p
\end{aligned}
$$

The λs are factor loadings and the terms $e_1, e_2, \dots, e_p$ are known as specific variates—they represent that part of an observed variable not accounted for by the common factors

(iii) The following assumptions are made:

(a) The common factors are in standardized form and have variance one

(b) The common factors are uncorrelated

(c) The specific variates are uncorrelated

(d) The common factors are uncorrelated with the specific variates

(iv) With these assumptions the factor analysis model implies that the population variances (σ_i^2, $j = 1, 2, \dots, p$) and covariances (σ_{ij}) of the observed variables can be written as

$$\sigma_i^2 = \sum_{j=1}^{k} \lambda_{ij}^2 + \psi_i$$

$$\sigma_i^2 = \sum_{l=1}^{k} \lambda_{il}\lambda_{jl}$$

where ψ_i is the variance of specific variate e_i, i.e., the specific variance of variable x_i

(v) The model implies that the variance of an observed variable can be split into two parts $\Sigma_{j=1}^{k} \lambda_{ij}^2$ and ψ_i. The first of those is known as the communality of the variable x_i; it is the variance in the variable shared with the other observed variables via their relationships with the common factors

(vi) Note that the covariances of the observed variables are generated solely from their relationships with the common factors. The specific variates play no part in determining the covariances of the observed variables; they contribute only to the variances of those variables

(vii) There are a number of different methods for fitting the factor analysis model. The two most commonly used are principal factor analysis and maximum likelihood factor analysis—both are described in Everitt and Dunn (1991)

(viii) A method of factor analysis commonly used in practice is principal components analysis (Everitt & Dunn, 1991). Although this is an extremely useful technique for the summarization of multivariate data, it is not discussed in detail here because it is not a natural precursor to the confirmatory and causal models to be discussed later. It may, however, be worthwhile listing the main differences between the two approaches:

(a) Factor analysis (FA) and principal components analysis (PCA) each attempt to describe a set of multivariate data in a smaller number of dimensions than one starts with, but the procedures used to achieve this goal are essentially quite different in the two approaches

(b) FA, unlike PCA, begins with a hypothesis about the covariance (or correlational) structure of the variables, namely that there exists a set of k latent variables ($k < p$) and these are adequate to account for the interrelationships of the variables though not for their full variances

(c) PCA, however, is merely a transformation of the data and no assumptions are made about the form of the covariance matrix of the data. In particular PCA has no part corresponding to the specific variates of FA. Consequently, if the FA model holds and the specific variances are small, both forms of analysis would be expected to give similar results

(d) A clear advantage of FA over PCA is that there is a simple relationship between the solutions obtained from the covariance and correlation matrices

(e) It should be remembered that PCA and FA are both pointless if the observed variables are uncorrelated—FA because it has nothing to explain and PCA because it would lead to components which are essentially identical to the original variables

(ix) In many (perhaps most) examples the results from a principal components analysis and an exploratory factor analysis will be similar, with any differences not usually affecting the substantive interpretation

Table 5 Pain statements and their correlations.

Pain statements

(1) Whether or not I am in pain in the future depends on the skills of the doctors
(2) Whenever I am in pain, it is usually because of something I have done or not done
(3) Whether or not I am in pain depends on what the doctors do for me
(4) I cannot get any help for my pain unless I go to seek medical advice
(5) When I am in pain I know that it is because I have not been taking proper exercise or eating the right food
(6) People's pain results from their own carelessness
(7) I am directly responsible for my pain
(8) Relief from pain is chiefly controlled by the doctors
(9) People who are never in pain are just plain lucky

Variance	3.007	1.502	0.619		

from the value one gives the specific variance of a variable, that is, the variation in the variable *not* shared with the other variables. So, for example, in the two factor solution the communality of the statement "people who are never in pain are just plain lucky," is rather low at 0.23 and its specific variance consequently relatively high at 0.77. Variation in the response to this statement is largely unrelated to the two common factors.

The sum of squares of the loadings on a common factor gives the variation in the manifest variables accounted for by that factor. This is to be compared with the total variation in the observed variables, which since this example uses a correlation matrix and hence relates to variables standardized to have variance one, is simply equal to the number of variables, that is, nine. So, in the two-factor solution, the first factor has variance 2.95 and accounts for 33% of the variation in the observed variables. Both factors together in the two-factor solution account for 49% of the variance. The factors in the three-factor solution together account for 57% of the variance.

Note that factors are extracted in order of their variance, and are so constructed that they are uncorrelated, that is, independent—an alternative technical term that is sometimes encountered is "orthogonal."

3.13.3.1.2 Determining the number of factors

Before rotating and interpreting a factor solution the investigator needs to answer the important question, "How many factors?" A variety of informal and formal methods have been suggested. The former include, taking as many factors as account for an adequate amount of the variation in the observed variables (where "adequate" is usually interpreted as roughly around 60% or above), and plotting factor variances against factor number (a so-called scree plot) and identifying the point where the curve flattens out. When applying the maximum likelihood method of factor analysis a more formal significance testing procedure is available based on what is known as the likelihood function, which is essentially, a measure of how well the estimated factor solution fits the observed correlations. Everitt and Dunn (1991) give a specific definition. With this approach a sequential procedure is used to determine k, the number of common factors. Starting with some small value of k (usually one), the test for number of factors is applied and, if the test is nonsignificant, the current value of k is deemed acceptable; otherwise k is increased by one and the process repeated until an acceptable solution is found.

Each of the procedures described above can be applied to the pain statements data, and the results are shown in Table 7 and Figure 1. It is clear from these results that the three-factor solution is the one to choose and is consequently subjected to the process of rotation described in the next section.

3.13.3.1.3 Factor rotation

The initial factors extracted from a factor analysis are often difficult to interpret and

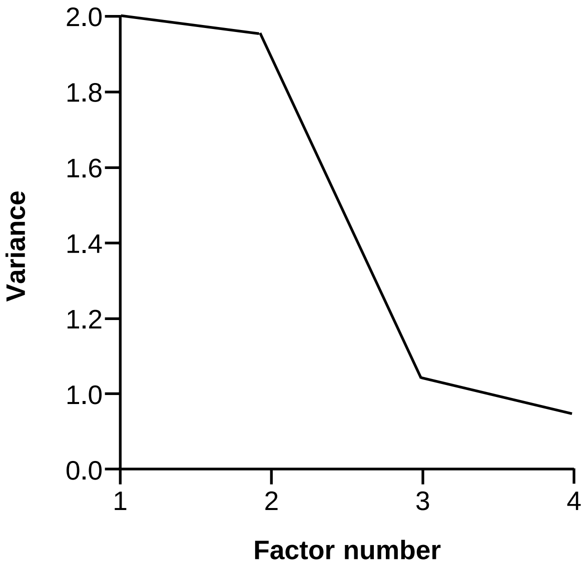

Figure 1 Scree plot.

Table 7 Determining number of factors for pain statement data.

(i) Percentage variance accounted for in a five-factor solution

Number of factors	*Percentage variance accounted for*
1	22
2	44
3	55
4	65
5	70

(ii) Significance test for number of factors

Model	*Test statistic*	*Degrees of freedom*	*P-value*

Two-factor	58.95	19	< 0.001
Three-factor	18.19	12	0.11
Four-factor	10.01	6	0.124
Five-factor	0.85	1	0.356

name. A process which can frequently aid in these tasks is factor rotation whereby the initial solution is described in a different and, in many cases, a simpler fashion. A rotated and unrotated factor analysis solution are mathematically equivalent, but the former usually leads to a clearer picture of the nature of the underlying latent variables. The rotation methods usually employed are designed to lead to a factor solution with the properties that Thurstone (1947) referred to as a simple structure. In very general terms such a structure results when the common factors involve subsets of the original variables with as little overlap as possible, i.e., variables have high loadings on a particular factor and negligible loadings on the others. In this way the original variables are divided into groups relatively independent of each other. Methods of rotation operate by seeking, essentially, to make large loadings larger and small loadings smaller. This rather vague aim is translated into more specific mathematical terms by selecting a rotated solution so that the loadings optimize some suitable numerical criterion. For example, a well known method of rotation known as varimax attempts to maximize the within-factor variance of the squared loadings. Other methods (of which there are several) choose to optimize somewhat different criteria in their aim to achieve simple structure. In many examples the solutions given by the competing methods of rotation will be very similar.

To illustrate the application of rotation, Table 8 shows the varimax-rotated, three-factor solution for the pain statement data. Note that although the factor loadings have changed, the communalities of the variables are unaltered, as is the total variance accounted for by the solution. The variance attributable to each common factor, *has* however, changed.

A possible interpretation of the rotated three-factor solution is in terms of different aspects of the control of, and responsibility for, one's pain. The first factor attributes both to others, particularly doctors. The second factor, with high loadings on statements 6 and 7, involves complete personal responsibilty for one's pain and the third factor, having its highest loadings on statements 2 and 5, might be seen as attributing pain to deficiencies in one's lifestyle.

The possibility of rotating factor solutions arises because of the lack of uniqueness of the factor loadings in the basic factor analysis model described in Table 5 (Everitt, 1996). This property once caused many statisticians to view factor analysis with grave suspicion, since apparently it allows investigators licence to consider a large number of solutions (each corresponding to a different rotation of the factors) and to select the one closest to their *a priori* expectations (or prejudices) about the factor structure of the data. In general, however, such suspicion is misplaced and factor rotation can be a useful procedure for simplifying an exploratory factor analysis solution. Factor rotation merely allows the fitted factor analysis model to be described as simply as possible. Rotation does not alter the overall structure of a solution, but only how the

Table 8 Rotated three-factor solution for pain statement data.

solution is described; rotation of factors is a process by which a solution is made more interpretable without changing its underlying mathematical properties.

It should be noted that there are two distinct types of rotation, orthogonal and oblique. With the former, the factors in the rotated solution remain independent of one another as they were in the initial solution but, with the latter, correlated factors are allowed. The consequence of allowing correlations between factors is that the sum of squares of a factor's loadings can no longer be used to determine the amount of variance attributable to a factor. Additionally, the sums of squares of factor loadings for each variable no longer give the communality of the variable. In practice, in an exploratory factor analysis, orthogonal rotation is far more commonly used than oblique rotation since the solutions are often satisfactory without introducing the complication of factor correlations.

3.13.3.2 Confirmatory Factor Analysis

In a confirmatory factor analysis, particular parameters of the model, for example, some of the factor loadings, are specified *a priori* to be fixed at some specified value, usually zero or one, whilst other parameters are free to be estimated from the data. The model considered may have arisen from theoretical considerations, or perhaps on the basis of the results of earlier exploratory factor analyses in the same area.

How is such a model fitted to an observed correlation or covariance matrix? The simple answer is by using the appropriate software as described in the Appendix. The essentials of the fitting process are, however, also given in Table 9. Once again, however, much can be learnt from examining a series of examples.

3.13.3.2.1 Confirmatory factor analysis models for length and intelligence

Consider once again the string data given in Table 3. The model suggested previously for these data is that the four observed measurements of string length are fallible estimates of the latent variable true string length. This model can be represented more specifically in mathematical terms as shown in Table 10, and in the form of a diagram as shown in Figure 2. The model is a very simple example of a confirmatory factor analysis model, and differs from the exploratory models considered in the previous section in two ways: (i) the number of factors, one, is specified *a priori*; and (ii) the loadings of the observed variables on the postulated latent variable are all fixed to be one.

The correlations between the four measurements are given in Table 11. Applying the procedure outlined in Table 9 to these correlations using the EQS package (Bentler, 1995), gives the results shown in Table 12.

Judged by the chi-squared statistic the model fits very well. As was to be expected, measurement by ruler is the most accurate; observer B appears to be the marginally less successful than G and D in guessing the string lengths. The residuals are all very small.

In the same way, the model detailed in Table 9 can be fitted to the examination scores data in Table 1. Details of the results are shown in Table 13. Here the model again fits reasonably well as judged simply by the chi-squared statistic, but rather less satisfactorily than for the string data, reflecting the less certain nature of intelligence as compared to length. In fact, the residuals in Table 13 indicate that the predicted and observed correlations differ quite considerably and that the model cannot really be considered adequate for these data despite the nonsignificant chi-squared value. The latter may be misleading here since it is not strictly

Table 9 Estimation and goodness of fit in confirmatory factor analysis models.

(i) Suppose that **S** is the observed covariance (or correlation) matrix with elements s_{ij}. Corresponding to **S** will be a matrix $\hat{\mathbf{S}}$ giving the correlations as predicted by the assumed model

(ii) The elements of the matrix $\hat{\mathbf{S}}$ will be functions of the parameters of the confirmatory factor analysis model, for example, factor loadings, specific variances, and factor correlations

(iii) Estimation of a confirmatory factor analysis (CFA) model involves finding values for the model's parameters (parameter estimates) so that the corresponding predicted and observed covariances and variances are as close as possible to one another

(iv) More specifically, a function of the differences between s_{ij} and $\hat{s}_{ij}$ is minimized with respect to the parameters

(v) One such function would be the sum of squares of the differences; this corresponds to least-squares estimation

(vi) Other estimation criteria are discussed in Everitt (1984)

(v) Having decided on a measure of closeness, some type of mathematical optimization algorithm (Everitt, 1987) is applied to find the parameter values that minimize the measure

(viii) The fitting procedure leads not only to parameter estimates but also to the standard errors of the estimates

(ix) A chi-squared statistic measuring the discrepancies between the observed variances and covariances and those predicted by the model is one of the methods that can be used to assess the fit of the model. The degrees of freedom are

$$\nu = p(p + 1)/2 - t$$

where p is the number of observed variables and t is the number of free parameters in the model

(x) Fit can (and should) also be assessed by examining the differences between the corresponding elements of the observed and predicted covariance or correlation matrix. Any differences (residuals) which are unacceptably large, or a pattern of moderately sized residuals sheds some doubt on the acceptability of the model

valid for samples as small as 15. Questions of the appropriate sample size necessary to achieve an adequate statistical power are as relevant when fitting confirmatory factor analysis as when applying a simple t-test (examples of how to determine sample size for the former are given in Dunn, Everitt, & Pickles, 1993).

A natural question that arises therefore is how the model might be amended to improve its fit. Some general points about how poorly fitting models might be amended are made later, but one relatively minor change that might be considered here is to allow the loading on each examination score to be a free parameter to be estimated rather than having a fixed value of one. Such a model is again easily fitted using the EQS software and the results are given in Table 14. Now the residuals are much more acceptable with only the correlation between algebra and statistics scores being poorly predicted. The estimated factor loadings show that the algebra scores are least related to the postulated latent variable.

3.13.3.2.2 Ability and aspiration

As a further example of fitting a confirmatory factor analysis model, the study of ability and aspiration described in Caslyn and Kenny (1977) is used. In this study the investigators observed the values of the following six variables for 556 white eighth-grade students: (1) self-concept of ability, (2) perceived parental evaluation, (3) perceived teacher evaluation, (4) perceived friend's evaluation, (5) educational aspiration, and (6) college plans.

The correlations between the six variables are given in Table 15. The model postulated to explain these correlations involves two latent variables, named by the authors as ability and aspiration. The first four observed variables are assumed to be indicators of ability and the last two observed variables are assumed to be indicators of aspiration. In addition the two latent variables are assumed to be correlated. Consequently the model is known as a correlated two-factor model. It may be represented in a diagram (a so-called path diagram (Everitt, 1996)) as shown in Figure 3. The mathematical form of the model appears in Table 16. Note again the differences between this model and the exploratory models of Section 3.13.3.1; here, each observed variable is constrained to have fixed zero loadings on one of the latent variables, and on the other, a free loading to be estimated from the data. The results of fitting the model to the observed correlations, using once again the EQS package, are shown in Table 17. Of particular note among these results is the estimate of the correlation between the two postulated latent variables. This estimate

Table 10 Mathematical specification of one-factor model for string data.

The factor analysis model for the string length data is

$$\begin{aligned} R &= f + e_1 \\ G &= f + e_2 \\ B &= f + e_3 \\ D &= f + e_4 \end{aligned}$$

where f represents the true length and e_1, e_2, e_3, and e_4 are the errors in the four observed length measurements. These errors are assumed to have zero mean and their estimated variances will reflect the accuracy of R, G, B, and D

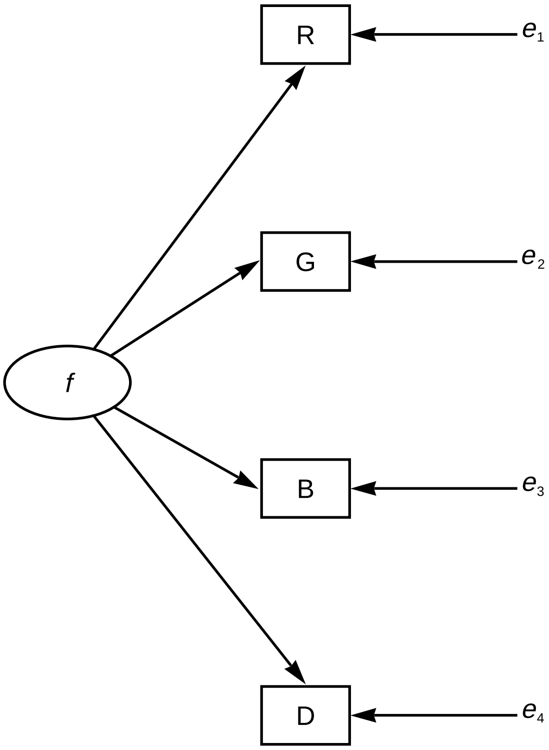

Figure 2 Single-factor model for string lengths.

(0.666 with a standard error of 0.03) is the disattenuated correlation, which represents the correlation between true ability and true aspiration, uncontaminated by measurement error in the observed indicators of these concepts. Note that the value of the disattenuated correlation is higher than any of the observed correlations.

3.13.3.2.3 Drug usage among American students

As a final example of fitting a confirmatory factor analysis model, an investigation of drug usage among American college students reported by Huba, Wingard, and Bentler (1981) is considered.

The majority of adult and adolescent Americans use psychoactive substances during an increasing proportion of their lifetime. Various forms of licit and illicit psychoactive substance use are prevalent, suggesting that patterns of psychoactive substance taking are major components of the individual's behavioral repertoire and have pervasive implications for the performance of other behaviors. In an investigation of these phenomena, Huba et al. (1981) collected data on drug usage rates for 1634 students in the seventh to ninth grades in 11 schools in the greater metropolitan area of Los Angeles. Each participant completed a questionnaire about the number of times he or she had ever used a particular substance.

Table 11 Correlation matrix for the four measurements of string length.

$$\mathbf{R} = \begin{array}{c} \\ R \\ G \\ B \\ D \end{array} \begin{array}{c} \begin{array}{cccc} \text{R} & \text{G} & \text{B} & \text{D} \end{array} \\ \left[\begin{array}{cccc} 1.0000 & & & \\ 0.9802 & 1.0000 & & \\ 0.9811 & 0.9553 & 1.0000 & \\ 0.9899 & 0.9807 & 0.9684 & 1.0000 \end{array}\right] \end{array}$$

Table 12 Results from fitting one-factor model with equal loadings for each variable to string data.

(i) Residuals (differences between observed and predicted correlations)

$$\mathbf{R} = \begin{array}{c} \\ R \\ G \\ B \\ D \end{array} \begin{array}{c} \begin{array}{cccc} \text{R} & \text{G} & \text{B} & \text{D} \end{array} \\ \left[\begin{array}{cccc} 0.007 & & & \\ -0.010 & -0.025 & & \\ -0.009 & -0.035 & -0.028 & \\ 0.000 & -0.009 & -0.022 & -0.007 \end{array}\right] \end{array}$$

(ii) Variances of error terms for each observed variable and their standard errors (SE)

R: variance = 0.003, SE = 0.005
G: variance = 0.035, SE = 0.014
B: variance = 0.038, SE = 0.016
D: variance = 0.017, SE = 0.008

(iii) Chi-squared goodness of fit statistic = 2.575, degrees of freedom = 5, *P*-value = 0.765

The substances for which data were collected were as follows: (1) cigarettes, (2) beer, (3) wine, (4) spirits, (5) cocaine, (6) tranquilizers, (7) drugstore medications used to get high, (8) heroin and other opiates. (9) marijuana, (10) hashish, (11) inhalents (glue, petrol, etc.), (12) hallucinogenics (LSD, mescalin, etc.), and (13) amphetamine stimulants.

Responses were recorded on a five-point scale which ranged from "never tried" to "used regularly." The correlations between the usage rates of the 13 substances are shown in Table 18. The model proposed by Huba et al. (1981) for these data arose from considering previously reported research in the area, and postulated the following three latent variables:

(i) Alcohol use (f_1) with nonzero loadings on beer, wine, spirits, and cigarettes.

(ii) Cannabis use (f_2) with nonzero loadings on marijuana, hashish, cigarettes, and wine. The cigarette variable is assumed to load on both the first and second latent variable because it sometimes occurs with both alcohol and marijuana and at other times does not. The nonzero loading on wine was allowed because of reports that wine is frequently used with marijuana and that consequently some of the use of wine may be an indicator of tendencies towards cannabis.

(iii) Hard drug use (f_3) with nonzero loadings on amphetamines, tranquilizers, hallucinogenics, hashish, cocaine, heroin, drugstore medication, inhalants, and spirits. The use of

Table 13 Results of fitting the one-factor model to examination scores, with loadings fixed at one.

(ii) Correlations

(ii) Residuals

$$\begin{array}{l|cccc|} & \text{English} & \text{French} & \text{Algebra} & \text{Statistics} \\ \text{English} & -0.113 & & & \\ \text{French} & 0.104 & 0.147 & & \\ \text{Algebra} & -0.293 & -0.128 & -0.265 & \\ \text{Statistics} & -0.148 & 0.111 & -0.035 & 0.025 \end{array}$$

(iii) Variances of error terms for each observed variable and their standard errors

English: variance = 0.534, SE = 0.244
French: variance = 0.274, SE = 0.156
Algebra: variance = 0.686, SE = 0.299
Statistics: variance = 0.396, SE = 0.196

(iv) Chi-squared goodness-of-fit statistic = 4.136, degrees of freedom = 5, *P*-value = 0.530.

each of these substances was considered to suggest a strong commitment to the notion of psychoactive drug use.

The path diagram of the proposed model is shown in Figure 4, and Table 19 shows the equivalent mathematical structure of the model. Note that each pair of the postulated variables is allowed to have a nonzero correlation. The results of fitting the model are detailed in Table 20. The chi-squared goodness-of-fit statistic takes a value 323.96 with 58 degrees of freedom and has a very small associated *P*-value. It appears that the proposed model does *not* provide an adequate explanation for the correlations between the recorded usage rates of the 13 substances, although the large sample size ($n = 1634$) may lead to even relatively trivial discrepancies between observed and predicted correlations being declared significant. In practice the chi-squared statistic is only one of the pieces of evidence that should be used when judging the fit of a model; other measures of fit are discussed in Dunn et al. (1993).

Amending a model that is considered not to provide an adequate fit will generally involve a mixture of the theoretical and empirical. Information from the data about possibly better fitting models is provided by two types of tests, the Lagrange multiplier test and Wald's test, both of which are described in detail in the EQS manual (Bentler, 1995). Essentially, however, the former evaluates whether, from a statistical viewpoint at least, the model could be improved by freeing a previously fixed parameter. The latter is designed to determine whether sets of parameters that were treated as free in the model could in fact be simultaneously set to zero without substantial loss in model fit. Examples of the use of the two test procedures are given in Dunn et al. (1993). In

Table 14 Results of fitting further single-factor model to examination scores; loadings now free parameters to be estimated.

(i) Residuals

$$\begin{array}{l c} & \begin{array}{cccc} \text{English} & \text{French} & \text{Algebra} & \text{Statistics} \end{array} \\ \begin{array}{l} \text{English} \\ \text{French} \\ \text{Algebra} \\ \text{Statistics} \end{array} & \left[\begin{array}{cccc} 0.000 & & & \\ 0.010 & 0.000 & & \\ -0.052 & -0.016 & 0.000 & \\ -0.070 & -0.002 & 0.197 & 0.000 \end{array} \right] \end{array}$$

(ii) Variances of error terms for each observed variable and their standard errors

(iii) Estimated factor loadings and their standard errors

English: loading = 0.698, SE = 0.247
French: loading = 0.965, SE = 0.225
Algebra: loading = 0.484, SE = 0.262
Statistics: loading = 0.718, SE = 0.246

(iv) Chi-squared goodness-of-fit statistic = 1.940, degrees of freedom = 2, P-value = 0.379

the original analysis of the drug usage data given in Huba et al. (1981) various amendments to the correlated three-factor model were tried in order to improve fit; for example, a number of error terms were allowed to be correlated. However, making such amendments to gain small improvements in fit is not always satisfactory and it should perhaps be pointed out that, in most cases, a theoretically justifiable model that provides a less adequate fit than a model adjusted on an *ad hoc* basis, is likely to be preferred.

Recent examples of the application of confirmatory factor analysis in clinical psychology are given in Osman et al. (1995) and Hittner (1995).

3.13.4 CAUSAL MODELS AND STRUCTURAL EQUATION MODELING

The confirmatory factor analysis models described in the previous section are a subset of the models for correlational data that can now be fitted routinely using software such as EQS or LISREL (see Appendix). More complex models that specify regression-type relationships between latent variables, as well as how the manifest and latent variables are linked, have now been used in many areas from models of the female orgasm (Newcomb & Bentler, 1983) to models to represent both psychological and physical processess in cognitive functioning (Hines, Chiu, McAdams, Bentler, & Lipcamon, 1992).

Such models are most generally (and most suitably) referred to as structural equation models. However, since they are often used as a means of describing some prespecified causal theory of the structure of a set of variables of interest, they are also often labeled causal models where "causal" implies that a change in one variable is assumed to result in the change of another variable. No matter how convincing, respectable, and reasonable a path diagram and its associated model may appear, it is important to recognize that seldom do structural equation models provide any direct test of the causal

Table 15 Observed correlations for ability and aspiration example.

$$\begin{array}{ccc} & & \begin{array}{cccccc} 1 & 2 & 3 & 4 & 5 & 6 \end{array} \\ \mathbf{R} = & \begin{array}{c} 1 \\ 2 \\ 3 \\ 4 \\ 5 \\ 6 \end{array} & \left[\begin{array}{cccccc} 1.00 & & & & & \\ 0.73 & 1.00 & & & & \\ 0.70 & 0.68 & 1.00 & & & \\ 0.58 & 0.61 & 0.57 & 1.00 & & \\ 0.46 & 0.43 & 0.40 & 0.37 & 1.00 & \\ 0.56 & 0.52 & 0.48 & 0.41 & 0.72 & 1.00 \end{array} \right] \end{array}$$

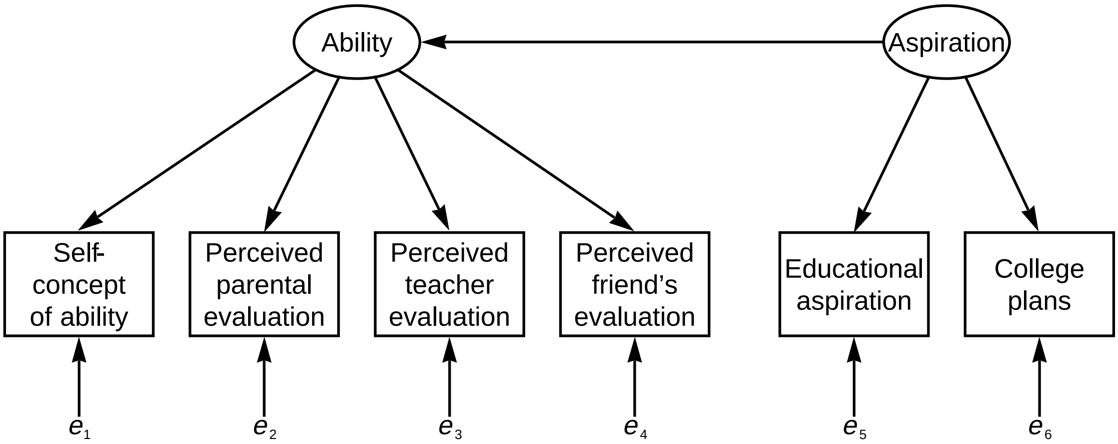

Figure 3 Path diagram for ability and aspiration.

assumptions on which these models are based. This is generally true simply because, in most cases, an investigator's belief about the causal structures which underlie a set of observed variables are based on little more than common sense and intuition; it is only rarely that there is strong evidence (such as that provided by controlled experimentation) about the causal structure involved, and the only satisfactory way to demonstrate causality is through the active control of variables. As pointed out by Cliff (1983) it is simply not possible, with correlational data, to isolate the empirical system sufficiently so that the nature of the relationships among variables can be unambiguously ascertained. It seems that the old aphorism much stressed in introductory statistics courses, "correlation does not imply causation" is still apposite even in the sophisticated world of structural equation modeling.

Many investigators proposing causal models might, of course, argue that they are using the term causal in a purely metaphorical fashion. As pointed out by deLeeuw (1985), however, such a cavalier attitude towards terminology becomes hard to defend if, for example, educational programs are based on the metaphors, such as "intelligence is largely genetically determined" or "allocation of resources to schools has only very minor impact on the careers of students."

Many of the problems of so called causal modeling mentioned above arise largely because of the relative lack of well specified causal theories in the social sciences. However, not all is doom and gloom for an investigator eager to try out such models. Although it may be the case

Table 16 Mathematical structure of correlated two-factor model for ability and aspiration.

(i) The two common factors or latent variables are ability (f_1) and aspiration (f_2) Both are assumed to have variance of one (this is necessary since they are unobserved and their scale needs to be set in some arbitrary way)

(ii) The proposed model postulates that the relationships between the observed variables and the latent variables are as follows:

$$\begin{aligned}
x_1 &= \lambda_1 f_1 + 0 f_2 + e_1\\
x_2 &= \lambda_2 f_1 + 0 f_2 + e_2\\
x_3 &= \lambda_3 f_1 + 0 f_2 + e_3\\
x_4 &= \lambda_4 f_1 + 0 f_2 + e_4\\
x_5 &= 0 f_1 + \lambda_5 f_2 + e_5\\
x_6 &= 0 f_1 + \lambda_6 f_2 + e_6
\end{aligned}$$

(iii) This may be rewritten as

$$\begin{aligned}
x_1 &= \lambda_1 f_1 + e_1\\
x_2 &= \lambda_2 f_1 + e_2\\
x_3 &= \lambda_3 f_1 + e_3\\
x_4 &= \lambda_4 f_1 + e_4\\
x_5 &= \lambda_5 f_2 + e_5\\
x_6 &= \lambda_6 f_2 + e_6
\end{aligned}$$

(iv) Note that, unlike an exploratory factor analysis, a number of loadings are fixed *a priori* at zero, that is, they play no part in the estimation process

(v) The model also allows for f_1 and f_2 to be correlated

(vi) The model has a total of 13 free parameters (six loadings, six error variances and one correlation). The observed correlation matrix has six variances and 15 correlations, a total of 21 terms. Consequently the postulated model has $21 - 13 = 8$ degrees of freedom

Table 17 Results from fitting the correlated two-factor model to correlations in Table 15.

Parameter	*Estimates*	*Standard error*	*Estimate/standard*
λ_1	0.863	0.035	24.558
λ_2	0.849	0.035	23.961
λ_3	0.805	0.035	22.115
λ_4	0.695	0.039	18.000
λ_5	0.775	0.040	19.206
λ_6	0.929	0.039	23.569
var(e_1)	0.255	0.023	19.911
var(e_2)	0.279	0.024	11.546
var(e_3)	0.352	0.027	13.070
var(e_4)	0.516	0.035	14.876
var(e_5)	0.399	0.038	10.450
var(e_6)	0.137	0.044	3.152
corr(f_1, f_2)	0.667	0.031	21.521

The chi-square test of the fit of the model takes the value 9.26 with 8 degrees of freedom. The associated *P*-value is 0.321. The model provides a very adequate fit for the data.

12	0.100	0.088	0.074	0.139	0.279	0.367	0.232	0.320	0.204	0.368	0.340	1.000	
13	0.245	0.199	0.184	0.293	0.278	0.545	0.232	0.314	0.394	0.467	0.392	0.511	1.000

Table 19 Mathematical structure of the correlated three-factor model for the drug usage data.

(i) Three latent variables, alcohol use (f_1), cannabis use (f_2), and hard drug use (f_3) are postulated. All are assumed to have variance unity

(ii) The proposed model postulates the following relationship between the observed and latent variables:

$$\begin{aligned}
\text{cigarettes} &= \lambda_1 f_1 + \lambda_2 f_2 + e_1 \\
\text{beer} &= \lambda_3 f_1 + e_2 \\
\text{wine} &= \lambda_4 f_1 + \lambda_5 f_2 + e_3 \\
\text{spirits} &= \lambda_6 f_1 + \lambda_7 f_3 + e_4 \\
\text{cocaine} &= \lambda_8 f_3 + e_5 \\
\text{tranquilizers} &= \lambda_9 f_3 + e_6 \\
\text{drugstore} &= \lambda_{10} f_3 + e_7 \\
\text{heroin} &= \lambda_{11} f_3 + e_8 \\
\text{marjuanna} &= \lambda_{12} f_2 + e_9 \\
\text{hashish} &= \lambda_{13} f_2 + \lambda_{14} f_3 + e_{10} \\
\text{inhalants} &= \lambda_{15} f_3 + e_{11} \\
\text{hallucinogenics} &= \lambda_{16} f_3 + e_{12} \\
\text{amphetamines} &= \lambda_{17} f_3 + e_{13}
\end{aligned}$$

(iii) The proposed model also allows for nonzero correlations between each pair of latent variables. The proposed model has a total of 33 parameters to estimate (17 loadings, 13 error variances, and 3 between-factor correlations). Consequently, the model has $13 \times 14/2 - 33 = 58$ degrees of freedom

that correlation does not imply causation, it is equally true that a well specified causal model implies testable propositions about the structure of observed correlations, and so is amenable to falsification in the same way as is any other scientific theory. At the very least, such a model may provide a convenient and parsimonious description of a set of correlations and serve to rule out many alternative hypotheses about the structure of the data.

3.13.4.1 Examples of Causal Models

After the rather lengthy discussion of their merits or otherwise given above, it is now time to look at some examples of the application of structural equation/causal modeling.

3.13.4.1.1 Ability scores over time

Table 21 gives, for a group of children, the means, standard deviations, correlations and covariances for four measures of ability (percentage of test questions correct) made at the ages of 6, 7, 9, and 11 (Osbourne & Suddick, 1972). As one would expect, the means increase progressively over time, as do the standard deviations. The correlation matrix shows higher correlations between adjacent measures than between those further apart in time.

The simplest model that might be considered for these data is that specified by the path diagram shown in Figure 5; here, ability is assumed to be a fixed trait and that variation over time arises solely from measurement error. Fitting such a model to the covariance matrix in

Table 20 Results of fitting the correlated three-factor model to the drug usage data.

Parameter	*Estimates*	*Standard error*	*Estimate/standard error*

corr(f_1,f_3)	0.313	0.029	10.674
corr(f_2,f_3)	0.499	0.027	18.412

Table 21 gives the results shown in Table 22. The chi-squared goodness-of-fit statistic is significant at the 5% level, suggesting that the simple single factor model does not provide an adequate fit for the covariance matrix.

In this example, the observed covariance matrix has been used as the basis for fitting the model of interest. In general the question of whether the covariance or correlation matrix should be used as the basis for structural equation modeling is probably not of great importance, although there are some situations where the covariance matrix is definitely to be preferred (Cudeck, 1989).

A path diagram for a more plausible model for the ability data is shown in Figure 6; this model postulates causal effects between one latent variable and another and the presence of the disturbances terms on f_2, f_3, and f_4 (terms d_2, d_3, and d_4) means that latent ability is not regarded as an entirely fixed and stable trait, but may vary, increasing or decreasing relative to other children, from one time to the next. The results of fitting this model are shown in Table 23. The chi-squared test statistic now indicates that the model fits satisfactorily. The regression coefficients of each latent variable on the one preceding it in time are all highly significant (see Dunn et al., 1993, for a detailed accident).

3.13.4.1.2 Stability of alienation

As a further example of structural equation modeling a study reported by Wheaton, Muthen, Alwin, and Summers (1977) is used. The study was concerned with the stability over time of attitudes such as alienation and their relationships to background variables such as

Table 21 Ability scores over time.

Statistic	*Age 6*	*Age 7*	*Age 9*	*Age 11*
Mean	18.034	25.819	35.255	46.593
Standard deviation	6.374	7.319	7.796	10.386

(i) Correlation matrix

$$\begin{array}{lcccc} & \text{Age 6} & \text{Age 7} & \text{Age 9} & \text{Age 11} \\ \text{Age 6} & 1.000 & & & \\ \text{Age 7} & 0.809 & 1.000 & & \\ \text{Age 9} & 0.806 & 0.850 & 1.000 & \\ \text{Age 11} & 0.765 & 0.831 & 0.867 & 1.000 \end{array}$$

(ii) Covariance matrix

$$\begin{array}{lcccc} & \text{Age 6} & \text{Age 7} & \text{Age 9} & \text{Age 11} \\ \text{Age 6} & 40.628 & & & \\ \text{Age 7} & 37.741 & 53.568 & & \\ \text{Age 9} & 40.052 & 48.500 & 60.778 & \\ \text{Age 11} & 50.643 & 63.169 & 70.200 & 107.869 \end{array}$$

education and occupation. Data were collected on attitude scales from 932 people in two rural regions in Illinois at three points in time (1966, 1967, and 1971). Only that part of the data collected in 1967 and 1971 will be of concern here and Table 24 shows the covariances between six observed variables. The anomia and powerlessness subscales are taken to be indicators of a latent variable, alienation, and the two background variables, education (years of schooling completed) and Duncan's socioeconomic index (SEI) are assumed to relate to a respondent's socioeconomic status. The path diagram for the model postulated to explain the covariances between the observed variables is shown in Figure 7. The model involves a combination of a confirmatory factor analysis model with a regression model for the latent variables. One of the important questions here involves the size of the regression coefficient of alienation in 1971 on alienation in 1967, since this reflects the stability of the attitude over time. Note that the error terms of anomia and powerlessness are allowed to be correlated over time to account for possible memory or other retest effects. Some of the results of fitting the proposed model are shown in Table 25.

The chi-squared goodness-of-fit statistic takes a value of 4.73 with four degrees of freedom and suggests that the proposed model fits the observed covariances extremely well. The estimated regression coefficient of alienation on socioeconomic status in both 1967 and 1971 is negative, as might have been expected since higher socioeconomic status is likely to result in lower alienation and vice versa. The

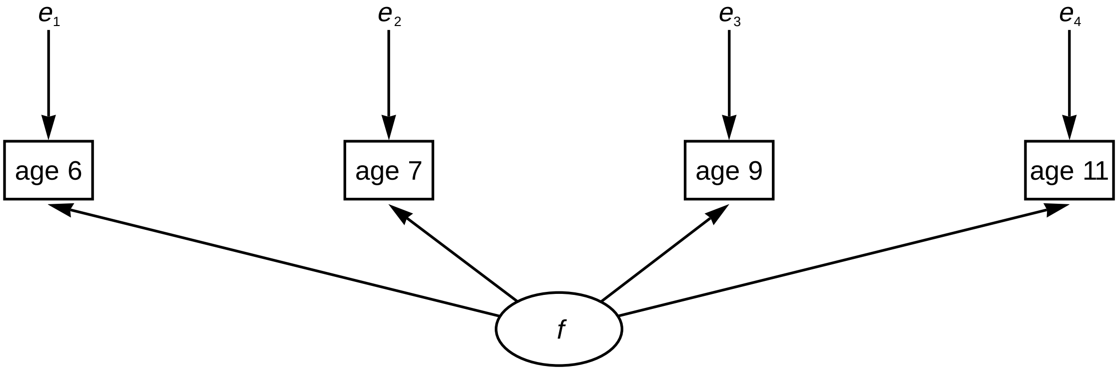

Figure 5 Single-factor model for ability data.

Table 22 Simple single-factor model—results for ability data.

Parameter	*Estimates*	*Standard error*	*Estimate/standard error*
λ_1	5.84	0.360	15.244
λ_2	6.684	0.397	16.842
λ_3	7.326	0.414	17.705
λ_4	9.476	0.564	16.813
var(e_1)	10.555	1.225	8.617
var(e_2)	8.89	1.197	7.427
var(e_3)	7.113	1.163	6.133
var(e_4)	18.084	2.424	7.460

(i) Chi-squared goodness-of-fit statistic 6.085, degrees of freedom = 2, *P*-value = 0.048.
(ii) Note that these estimates are obtained from the covariance matrix so that the factor loadings are no longer correlations between observed and latent variables. They now represent regression coefficients.
(iii) The statistical significance of each parameter can be judged by the *z*-statistics given in the final column. Values outside (–2,2) are roughly significant at the 5% level.

estimated regression coefficient for alienation in 1971 on alienation in 1967 is positive and highly significant. Clearly the attitude remains relatively stable over the time period.

An example of the application of structural equation modeling in clinical psychology is given in Taylor and Rachman (1994).

3.13.5 LATENT VARIABLES—MYTHS AND REALITIES

Having already commented in Section 3.13.4 that the "causal" in causal modeling is usually a misnomer, what can be said about the concept of a latent variable, central to the methods described in this chapter? In one sense, latent variables can never be anything more than is contained in the observed variables and never anything beyond what has been specified in the model. For example, in the statement that verbal ability is whatever certain tests have in common, the empirical meaning is nothing more than a shorthand for the observation of the correlations. It does not mean that verbal ability is a variable that is measurable in any manifest sense. In fact latent variables are essentially hypothetical constructs invented by a scientist for the purpose of understanding some research area of interest, and for which there exists no operational method for direct measurement. Consequently, a question that needs to be asked is "Can science advance by inferences based upon hypothetical constructs that cannot be measured or empirically tested?" According to Lenk (1986) the answer is a resounding "sometimes." For example, atoms in the eighteenth and nineteenth centuries were hypothetical constructs which allowed the foundation of thermodynamics; gravity and the electromagnetic field are further examples from physics. Clearly a science can advance using the concept of a latent variable, but their importance is not their reality or otherwise, but rather to what extent the models of which they are a part are able to describe and predict

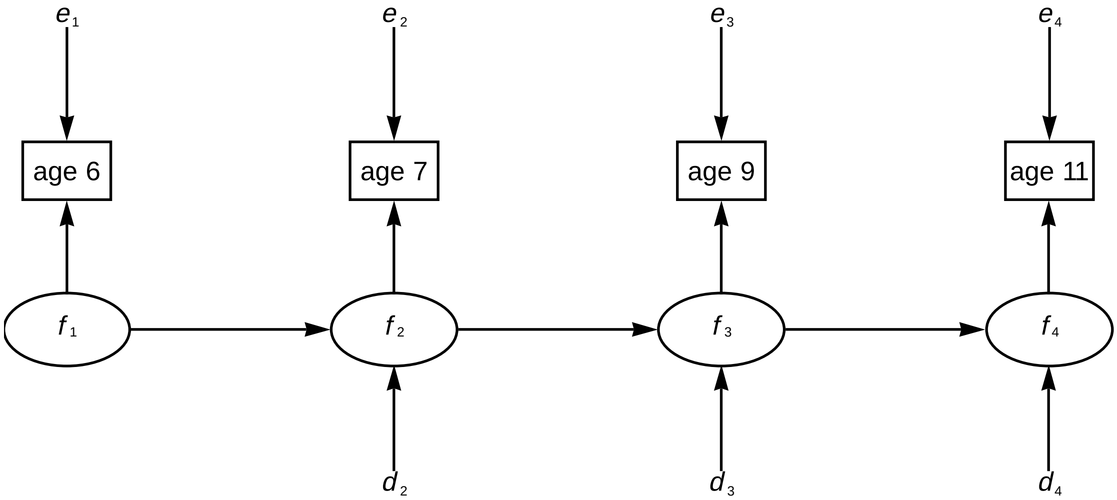

Figure 6 Causal model for ability data.

Table 23 Results from fitting causal model for ability data.

(i) Regression coefficients of latent variables on preceding latent variables

f_2 on f_1: 1.120, SE = 0.064
f_3 on f_2: 1.044, SE = 0.046
f_4 on f_3: 1.296, SE = 0.054

(ii) Chi-squared goodness-of-fit statistic = 1.433, degrees of freedom = 2, P-value = 0.489

phenomena (Lakatos, 1977). This point is nicely summarized by D. M. Fergusson and L. J. Horwood (personal communication, 1986):

> Scientific theories describe the properties of observed variables in terms of abstractions which summarize and make coherent the properties of observed variables. Latent variables, are, in fact, one of this class of abstract statements and the justification for the use of these variables lies not in an appeal to their "reality" or otherwise but rather to the fact that these variables serve to synthesize and summarize the properties of observed variables.

This point was also made by the participants in the Conference on Systems under Indirect Observation who concluded, after some debate (Bookstein, 1982) that latent variables are "as real as their predictive consequences are valid." Such a comment implies that the justification for postulating latent variables is their theoretical utility rather than their reality.

3.13.6 SUMMARY

The possibility of making causal inferences about latent variables has great appeal for the social and behavioural scientist, simply because many of the concepts in which they are most interested are not directly measurable. Many of the statistical and technical problems in applying the appropriate models to empirical data have largely been solved, and sophisticated software such as EQS means that researchers can investigate and fit extremely complex models routinely. Unfortunately, in their rush not to be left behind in the causal modeling stakes, many investigators appear to have abandoned completely their proper scientific skeptism, and accepted models as reasonable, simply because it has been possible to fit them to data. This would not be so important if it were not the case that much of the research involved is in areas where action, perhaps far-reaching action, taken on the basis of the findings of the research can have enormous implications, for example, in resources for education and

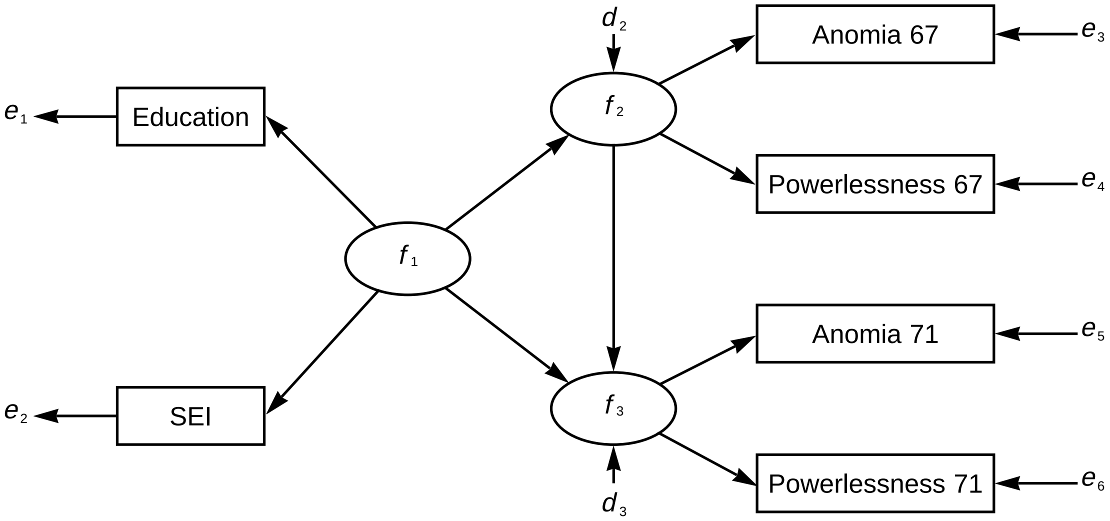

Figure 7 Causal model for stability of alienation.

Alienation 71 on socioeconomic status: –0.592, SE = 0.131

legislation on racial inequality. Consequently, both producers of such research and audiences or consumers of it need to be particularly concerned that the conclusions reached are valid ones. With this in mind I would like to end with the caveat issued by Cliff (1983, p.125):

> beautiful computer programs do not really change anything fundamental. Correlational data are still correlational, and no computer program can take account of variables that are not in the analysis. Causal relations can only be established through patient, painstaking attention to all the relevant variables, and should involve active manipulation as a final confirmation

ACKNOWLEDGMENT

I would like to thank Dr. Nina Schooler for many helpful suggestions which substantially improved this chapter.

Table 26 Identification examples.

(i) Consider three variables, x_1, x_2, and x_3, with correlation matrix R given by

$$\mathbf{R} = \begin{array}{c} \\ x_1 \\ x_2 \\ x_3 \end{array} \begin{bmatrix} x_1 & x_2 & x_3 \\ 1.00 & & \\ 0.83 & 1.00 & \\ 0.78 & 0.67 & 1.00 \end{bmatrix}$$

(ii) Suppose we are interested in fitting a single-factor model, that is

$$\begin{aligned} x_1 &= \lambda_1 f + e_1 \\ x_2 &= \lambda_2 f + e_2 \\ x_3 &= \lambda_3 f + e_3 \end{aligned}$$

(iii) There are seven parameters to be estimated, namely

$$\lambda_1,\ \lambda_2,\ \lambda_3,\ \text{var}(f),\ \text{var}(e_1),\ \text{var}(e_2),\ \text{var}(e_3)$$

(iv) There are, however, only six statistics for use in parameter estimation:

$$\text{var}(x_1),\ \text{var}(x_2),\ \text{var}(x_3),\ \text{corr}(x_1, x_2),\ \text{corr}(x_1, x_3),\ \text{corr}\ (x_2, x_3)$$

(v) Consequently, the model is underidentified

(vi) If var(f) is set equal to one then the model is just identified—there are exactly the same number of parameters to estimate as there are informative sample statistics

(vii) Equating observed and expected variances and correlations will give the required estimates:

$$\begin{aligned} \hat{\lambda}_1\hat{\lambda}_2 &= 0.83 \\ \hat{\lambda}_1\hat{\lambda}_3 &= 0.78 \\ \hat{\lambda}_2\hat{\lambda}_3 &= 0.67 \\ \widehat{\text{var}}(e_1) &= 1.0 - \hat{\lambda}_1^2 \\ \widehat{\text{var}}(e_2) &= 1.0 - \hat{\lambda}_2^2 \\ \widehat{\text{var}}(e_3) &= 1.0 - \hat{\lambda}_3^2 \end{aligned}$$

(where "hats" indicate estimates)

(ix) Solving these equations leads to the estimates

$$\hat{\lambda}_1 = 0.99,\ \hat{\lambda}_2 = 0.84,\ \hat{\lambda}_3 = 0.79,\ \text{var}(e_1) = 0.02,\ \text{var}(e_2) = 0.30,\ \text{var}(e_3) = 0.38$$

(x) Now consider an analogous measurement model with four observed variables and again set var(f) = 1 (this model is now the one used on the string data and the examination scores data)

(xi) Equating observed and expected variances and correlations in this case will lead to more than a single unique estimate for some of the parameters. The model is overidentified and represents a genuinely more parsimonious description of the structure of the data. Here a better strategy for estimation is clearly needed (see Table 9)

3.13.7 APPENDIX

Explanatory factor analysis methods such as principal factor analysis and maximum likelihood factor analysis are available in all major packages, for example, SPSS, SAS, MINITAB, and SYSSTAT. Options that need to be selected include (i) method of factor analysis, (ii) method of estimating initial communalities, and (iii) method of rotation.

For many examples the solutions given by a different combination of the available options will be very similar. In most cases the available software makes the derivation of the results of a factor analysis very simple; interpretation of these results is often, however, a different matter.

Confirmatory factor analysis and structural equation modeling are generally undertaken using either the LISREL or EQS package. The former is described in Jöreskog and Sörborm (1993) and the latter in Dunn et al. (1993). Using either piece of software requires some degree of understanding of how to translate proposed models into equations that specify the model explicitly (see Tables 10 and 19). One of the problems of structural equation modeling conveniently ignored in the text is that of model identification which refers to the degree to which there is a sufficient number of equations to solve for each of the parameters to be estimated. Models can be (i) underidentified (too few equations), (ii) just identified (no degrees of freedom remain for testing the fit of the model—the model will fit perfectly but will not give a more parsimonious description of the data than is provided by the observed correlations or covariances), or (iii) overidentified (more equations than parameters—the fit of model can be tested). Table 26 illustrates these different situations with a number of simple models, and a full discussion of identification is given in Dunn et al. (1993). In many cases the identification status of a complex model (and, at times, relatively simple models) is very difficult to ascertain *a priori.* Nonidentified models will cause problems for both EQS and LISREL and users need to be very wary of results which are accompanied by messages that point out that a parameter is, for example, at its lower or upper bound (i.e., a variance is zero or a correlation is one) or that some parameters are linearly dependent on others.

3.14.1 INTRODUCTION

A statistical wit once remarked that researchers often pose the wrong question and then proceed to answer that question incorrectly. Statistical analyses in psychological research traditionally have taken the form of significance tests. The near-universal use of significance tests has made them the *de facto* standard of proof in research and the logic that underlies significance tests has played an important role in shaping the development of psychological theory. In fact, though, significance tests are generally not appropriate for the kinds of questions that are addressed in psychological research. First, significance tests address the wrong question. Researchers are concerned with clinical significance (i.e., the magnitude of the effect) but significance tests address only statistical significance (whether or not the effect is zero). Second, the significance test, by focusing attention on the p-value, lends itself to mistakes of interpretation. Significant p-values are assumed to reflect clinically important effect sizes, while in fact a significant p-value may reflect a large sample size rather than a large effect size. Similarly, nonsignificant p-values are taken as evidence that the treatment has no impact, though this conclusion is almost always incorrect.

To address these issues researchers have been moving away from significance tests and toward effect size estimation. Rather than report that "$p=0.01$," the researcher would report that "the treatment improved the response rate by 20 percentage points (95% confidence interval of 0.15–0.25)." While there is widespread consensus that the shift toward effect size estimation is appropriate, there is considerable disagreement over the nature of the proposed shift. Some feel that the logic of the significance test should be retained, with the shift to the use of confidence intervals being one of format rather than substance. From this perspective, the confidence intervals serve as a surrogate for the significance test. Others argue that we need to rethink the role of the single study as an element in the research process, and that any vestige of the significance test should be excluded. From this perspective, confidence intervals serve as an index of precision only.

We also consider the implications of this paradigm for study planning. The discussion of significance tests is followed by a section on power analysis, which is used in study planning to ensure that the study will yield a statistically significant result. The discussion of effect size estimation is followed by a discussion of precision analysis, which may be used in study planning to ensure that the study will yield a precise estimate of the treatment effect.

3.14.2 THE SIGNIFICANCE TEST

3.14.2.1 The Logic of the Significance Test

Research trials are always carried out on a sample of finite size. The results obtained in the sample are assumed to be representative of the larger population but because of random sampling error will rarely, if ever, mirror that population exactly.

For example, consider a study whose goal is to determine whether or not a new drug being tested with acute schizophrenics yields a higher response rate than the current treatment. Assume that the drug really is effective, and (in the population) increases the response rate by 20 percentage points. The mean effect over an infinite number of samples would be 20 points, but the effect observed in any single sample would almost invariably fall somewhat below or above 20 points. Similarly, if the drug really has zero effect in the population then the mean effect over an infinite number of samples would be zero points, but the effect observed in any single sample would likely fall somewhat below zero (the response rate being lower for new drug), or above zero.

Therefore, if we run a study and observe a difference in response rates for the two groups, we need to determine whether or not the sample may have been drawn from the second population above (where the treatment effect is zero). To this end we pose the null hypothesis that the two treatments are equally effective. If the null hypothesis is true, then the effect observed in our sample, if not zero, should fall within a "reasonable" distance of zero. If our sample were to yield a rate difference that was "compelling," in the sense that it was not "reasonably close to zero," we would conclude that the assumption of equal response rates is not viable.

Our ability to conclude that the observed effect is "compelling" will depend on three factors, each of them intuitive. The first is the size of the effect. An observed difference of 40 points in response rates is more compelling than an observed difference of 20 points. The second is the size of the sample. An observed difference of 20 points may be discounted if based on a sample of 10 cases per group since a single aberrantly responding patient could pull the response rate by 10 percentage points in either direction. The same size effect would be more convincing in a sample of 40 patients per group, and would probably be seen as definitive in a study that employed 100 patients per group. The third element is the stringency of the criteria we require as evidence that a difference exists. If the treatment carried little risk of harm and was inexpensive, we might be willing to declare it "effective" even if the evidence was relatively weak. On the other hand, if it carried a nontrivial risk of harm or a high cost we might require that it meet a more stringent criterion.

This logic (how large is the effect, how large is the sample, how certain do I want to be) is formalized in the test of significance that is routinely applied to studies. Significance tests vary from one statistical procedure to the next but are all variations on the theme

$$\text{Test statistic} = \frac{\text{Observed difference}}{\text{Dispersion of the difference}}$$

The numerator in this equation is the observed difference, for example, a rate difference of 10 points or 20 points between groups. The denominator reflects the sample-to-sample dispersion expected in the numerator, and incorporates information about the sample size (when the sample is large, the expected dispersion is small). The test statistic is computed as the ratio of these two values. As such, it will be high when the observed effect is large and/or the sample size is large. In a sense, the test statistic serves as a kind of signal-to-noise ratio: if the population effect is zero we expect the sample effect to vary within some range of zero. The numerator in the equation reflects the observed effect and the denominator defines the expected range in which sample effects will normally fall. The test statistic tells us whether or not the sample effect falls outside the normal range.

The test statistic is compared with a table of values showing the expected range of the test statistic under the assumption that the null hypothesis is true. If our test statistic falls within this range, we cannot reject the null. If our test statistic falls outside this range, however, we would conclude that the null hypothesis is most likely false, and the treatment does have an effect. We need to decide what level of evidence we will require prior to rejecting the null, and this threshold is known as alpha. For example, if alpha is set at 0.05, then the study result will be deemed significant if, on the assumption that the null is true, the study effect (or larger) would be observed in only 5% of cases.

3.14.2.2 Errors of Inference

The significance test carries the potential for two types of error: We may reject as false a null hypothesis that in fact is true (type I error), or we may accept as true a null hypothesis that in fact is false (type II error).

3.14.2.2.1 Type I error

As noted earlier, study results would be declared "significant" if the sample effect was "compelling." The type I error rate is denoted by alpha. With alpha set at 0.05, over an infinite number of studies where the null is true, our sample will nevertheless meet the criterion and be declared significant in 5% of the studies. This situation—where the null is true but we decide in error that the treatment is effective—is referred to as a type I error.

This point is repeated for emphasis. There is a general perception that 5% of studies will result in a type I error, but this is not correct. When the null hypothesis is true 5% of studies will result in a type I error. However, if the treatment really is effective, then by definition a type I error is not possible and the type I error rate is zero.

3.14.2.2.2 Type II error

To meet the criterion for statistical significance a study must yield an effect size that is large enough to establish significance, given the sample size and the criterion alpha. Even if the treatment is effective, and even if the size of the effect is substantial (in the population and/or in the sample), there is no guarantee that the study will yield a statistically significant result. The effect observed in the sample may be smaller than the population effect (in half of all unbiased studies, it will be), which may yield a nonsignificant result. Indeed, even if the sample effect is as large (or larger) than the population effect, unless the sample size is adequate the results may not meet the criterion for statistical significance. The type II error rate is denoted by beta. If the treatment really is effective and beta is 0.20, then 20% of all studies will yield nonsignificant results.

3.14.3 POWER ANALYSIS

The likelihood that a study will yield a statistically significant effect is the study's power and the process of designing a study to ensure an appropriate level of power is referred to as a power analysis. If the purpose of the study is to test the null hypothesis, then a power analysis is a critical element in study planning, to ensure that the study will be able to meet this goal.

The statistical significance computed subsequent to the study is a function of three elements—effect size, sample size, and alpha. It follows that power, which reflects the likelihood that the study will yield statistical significance, is determined by the same three elements. Specifically, the larger the effect size used in the power analysis, the larger the sample size, and/or the more liberal the criterion required for significance (alpha), the higher the expectation that the study will yield a statistically significant effect. These three factors, together with power, form a closed system—once any three are established, the fourth is completely determined. The goal of a power analysis is to find an appropriate balance among these factors by taking into account the substantive goals of the study and the resources available to the researcher.

3.14.3.1 Role of Effect Size in Power Analysis

Power analysis gives power for a specific effect size. For example, the researcher might report "If the treatment increases the response rate by 20 percentage points the study will have power of 80% to yield a significant effect." For the same sample size and alpha, if the treatment effect is less than 20 points then power will be less than 80%. If the treatment effect exceeds 20 points, then power will exceed 80%.

Since our computation of power ensures, to some likelihood, that the study will succeed in rejecting the null given a specific effect size, it follows that the effect size used in the power analysis should represent the smallest effect that would be of clinical or substantive significance. In clinical trials, for example, the selection of an effect size might take account of the following factors:

(i) The severity of the illness being treated. If we are testing a treatment that will reduce the likelihood of relapse among schizophrenics, we might decide that a reduction of as little as 10% is clinically important since the implications of a relapse can be relatively severe. By contrast, if we are testing a treatment that was expected to reduce the likelihood of an anxiety attack, a 10% reduction might be of little clinical import since the attacks are transitory. In this case, we might decide that only a reduction of 20% or more is clinically important.

(ii) The availability of alternate treatments. If no treatments exist for a particular condition, then a treatment that was effective in even a small proportion of patients might be clinically important. By contrast, if treatments already exist for the condition, then a new treatment might need to surpass these to be considered clinically important. This might mean that the new treatment was effective in a larger proportion of affected persons, or had a larger impact for individual patients.

(iii) Treatment cost and side effects. In deciding what constitutes a clinically important effect we might want to take account of such issues as treatment costs and side effects. A drug that carried a risk of serious side effects or that carried a high price might be considered clinically useful only if it was effective in a substantially higher proportion of cases than available treatments, or was being used to treat a severe condition.

The factors that are taken into account for identifying a clinically important effect will of course vary from one study to the next and the three items mentioned above are intended only as examples. The general point is that the selection of an effect size should be made on the basis of substantive issues and that these will vary from one study to the next.

A study that has adequate power to detect a relatively large effect will not have adequate power to detect a small effect. By contrast, a study that has adequate power to detect a relatively small effect will, of course, have more than enough power to detect moderate or large effects. While one might therefore be tempted to set the "clinically important effect" at a small value to ensure high power for even a small effect, this determination cannot be made in isolation. Small effects will require a larger investment of resources than large effects. The selection of an effect size reflects the need for balance between the size of the effect that we can detect, and the resources available for the study. Figure 1 shows power as a function of sample size for three levels of effect size (assuming alpha, two-tailed, is set at 0.05). For the smallest effect (30% vs. 40%), we would need a sample of 376 per group to yield power of 80%. For the intermediate effect (30% vs. 50%), we would need a sample of 103 per group to yield this level of power. For the highest effect size (30% vs. 60%), we would need a sample of 49 per group to yield power of 80%. In this example we may decide that it would make sense to enroll 103 patients per group to detect the intermediate effect but inappropriate to enroll 376 patients per group to detect the smallest effect.

3.14.3.1.1 The effect size used in power analysis is not necessarily the population effect size

Researchers often assume that the effect size used in a power analysis is the "true" (population) effect size. In fact, though, the "true" effect size is not known. While the effect size in the power analysis is assumed to reflect the population effect size for the purpose of calculations, the power analysis is more appropriately expressed as "If the true effect is 20 percentage points power would be ... " rather than "The true effect is 20 percentage points, and therefore power is ... "

This distinction is an important one. Researchers sometimes assume that a power analysis cannot be performed in the absence of pilot data. In fact, it is usually possible to perform a power analysis based entirely on a logical assessment of what constitutes a clinically (or theoretically) important effect. Indeed, while the effect observed in prior studies might help to provide an estimate of the true effect it is not likely to be the true effect in the population—if we knew that the effect size in these studies was accurate, there would be no need to run the new study.

Since the effect size used in power analysis is not the "true" population value, the researcher may elect to present a range of power estimates. For example (assuming $N = 103$ per group and alpha = 0.05, two-tailed), "The study will have power of 80% to detect a treatment effect of 20 points (30% vs. 50%), and power of 99% to detect a treatment effect of 30 points (30% vs. 60%)."

The nature of the effect size will vary from one statistical procedure to the next. In all cases, however, it serves the same function of providing a pure index of the effect, that is, an index that focuses exclusively on the effect, independent of the sample size, and that is not affected by the metric in which the effect is measured.

3.14.3.1.2 Conventions for effect size

Cohen (1988, 1992) has suggested conventional values for "small," "medium," and "large" effects in the social sciences. For tests of a mean difference between two groups the effect size index is *d*, the standardized mean difference (i.e., mean difference divided by the

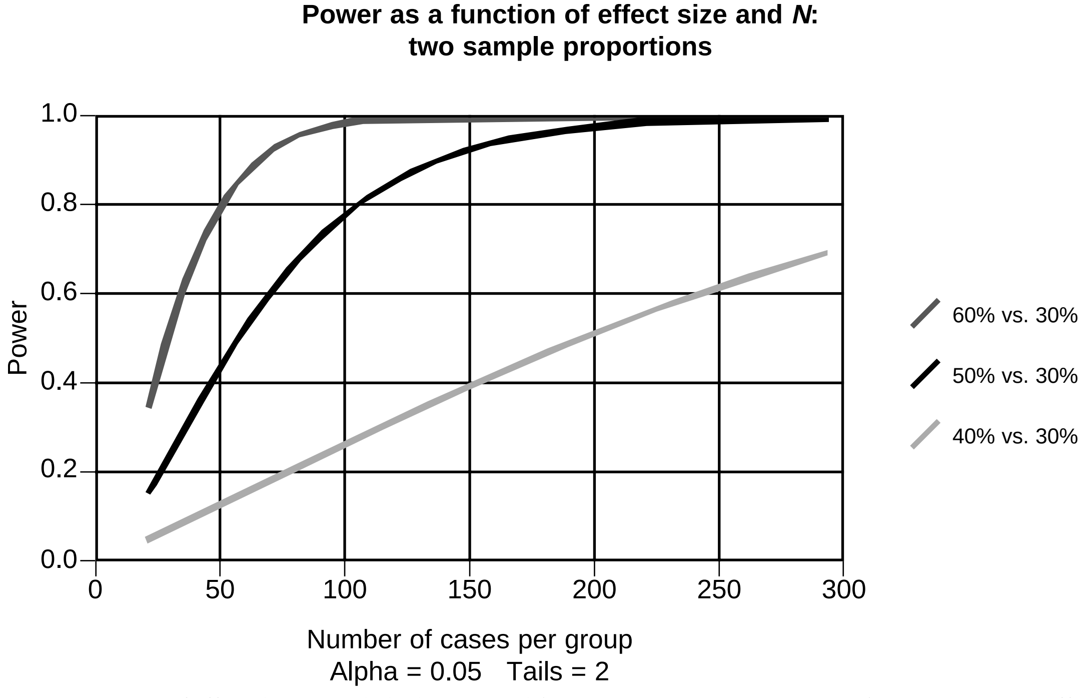

Figure 1 Impact of effect size on statistical power. With 100 cases per group, power to detect a treatment effect of 10 percentage points (response rates of 40% vs. 30%) is about 0.25, power to detect a treatment effect of 20 points is about 0.80, and power to detect a treatment effect of 30 points is about 0.99.

common within-group standard deviation). A "small" effect is given as $d = 0.20$ (i.e., 20% of the common within-group standard deviation); a medium effect as $d = 0.50$; and a large effect as $d = 0.80$. For tests of a difference between proportions a small effect is given as proportions of 40% vs. 50%; a medium effect corresponds to proportions of 40% vs. 65%; and a large effect corresponds to proportions of 40% vs. 78%. Note that the effect size for proportions cannot be specified simply by giving the difference between the two proportions, but requires that the absolute proportions be specified. For example, the effect size of 10% vs. 20% is larger than the effect size of 40% vs. 50%, despite the fact that the difference is 10 points in either case. For tests of a single correlation, the effect size is the correlation itself. A small effect is given as a correlation of 0.10, a medium effect is a correlation of 0.30, and a large effect is a correlation of 0.50. Cohen also provides conventions for other tests including analysis of variance and multiple regression. These conventions are also included in some computer programs (Borenstein & Cohen, 1988; Borenstein, Cohen, Rothstein, Pollack, & Kane, 1990, 1992; Borenstein, Rothstein, & Cohen, 1997; Rothstein, Borenstein, Cohen, & Pollack, 1990).

Cohen himself cautions that these conventions should not be used routinely, since it is preferable to select an effect size based on the substantive issues involved in the specific study (as above). Nevertheless, these conventions do serve two functions. In all cases the researcher may want to use these values as a kind of reality-check, to ensure that the values specified make sense relative to these anchors. Additionally, in cases where the researcher has difficulty deriving any kind of effect size index, they may elect to fall back on these conventions (see also Kraemer & Thiemann, 1987).

3.14.3.2 Role of Alpha in Power Analysis

The significance test yields a *p*-value that reflects the likelihood of obtaining an effect as large (or larger) than the observed effect, under the assumption that the null hypothesis is true. For example, a *p*-value of 0.02 means that, assuming that the treatment has no effect, and given the sample size, an effect as large as the observed effect would be seen in only 2% of studies. The *p*-value obtained in the study is evaluated against the criterion alpha. If alpha is set at 0.05, then a *p*-value of 0.05 or lower is required to reject the null hypothesis and establish statistical significance.

If our only concern in study design were to prevent a type I error, it would make sense to set alpha as conservatively as possible (e.g., at 0.001). However, alpha does not operate in isolation. If we select a more stringent criterion for alpha, then our ability to meet this criterion

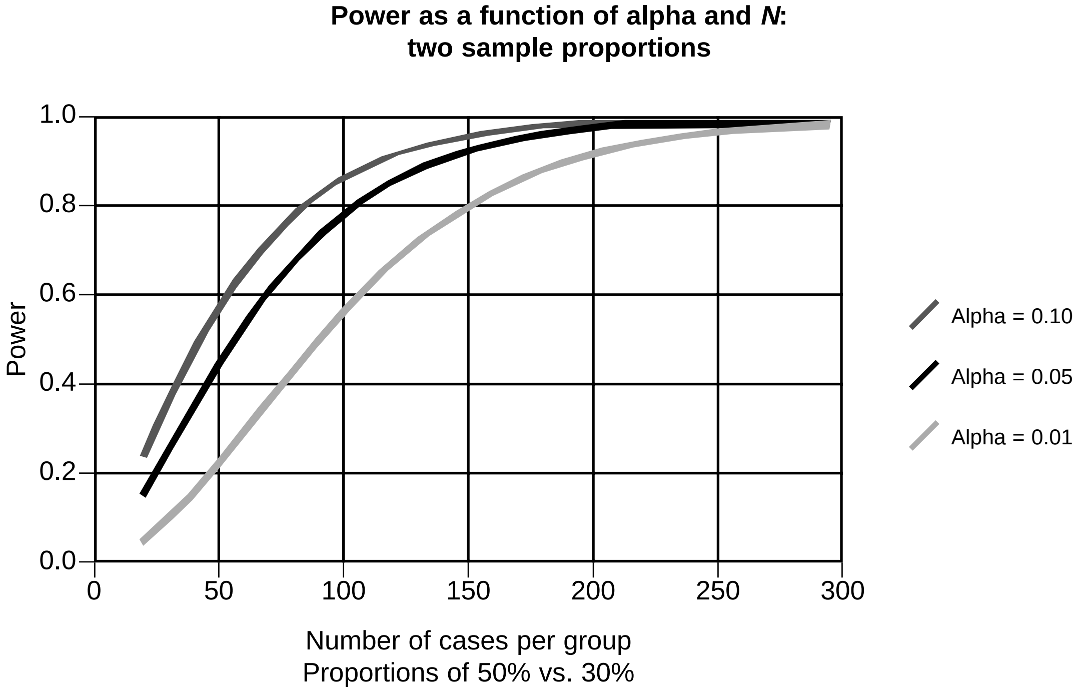

Figure 2 Impact of alpha on statistical power. With 100 cases per group and alpha set at 0.01, power is less than 0.60; with alpha at 0.05, power is about 0.80; and with alpha at 0.10, power is about 0.85. These computations are based on response rates of 50% vs. 30%, corresponding to the center line in Figure 1.

is reduced. By moving alpha from (say) 0.10 toward 0.01, we reduce the likelihood of a type I error but increase the likelihood of a type II error. (More accurately, and to emphasize a point made earlier: We reduce the likelihood of a type I error if the null is true, but increase the likelihood of a type II error if the null is false.)

Figure 2 shows power as a function of sample size for three levels of alpha (assuming an effect size of 30% vs. 50%, which is the intermediate effect size in the previous figure). With a sample size of 100 per group, with alpha set at 0.10 power exceeds 85%; with alpha set at 0.05 power is about 80%; and with alpha set at 0.01, power is under 60%.

Traditionally, researchers in some fields have accepted the notion that alpha should be set at 0.05 and power at 80% (corresponding to a beta of 0.20). This notion is implicitly based on the assumption that a type I error is four times as harmful as a type II error (the ratio of alpha to beta is 0.05–0.20), which notion has no basis in fact. Rather, it should fall to the researcher to strike a balance between alpha and beta as befits the issues at hand. For example, if the study will be used to screen a new drug for further testing we might want to set alpha at 0.20 and power at 95%, to ensure that a potentially useful drug is not overlooked. On the other hand, if we were working with a drug that carried the risk of side effects and the study goal was to obtain Federal Drug Administration (FDA) approval for use, we might want to set alpha at 0.05 while keeping power at 95%.

3.14.3.3 Role of Tails in Power Analysis

The significance test is always defined as either one- or two-tailed. A two-tailed test is a test that will be interpreted if the effect meets the criterion for significance and falls in either direction. As such, it is appropriate for the vast majority of research studies. A one-tailed test is a test that will be interpreted only if the effect meets the criterion for significance and falls in the expected direction (i.e., the treatment improves the cure rate).

A one-tailed test is appropriate only if an effect in the unexpected direction would be functionally equivalent to no effect. For example, assume that the treatment we are using for depression is relatively inexpensive and carries a minimal risk of side effects. We will be testing a new treatment which is more expensive but carries the potential for a greater effect. The possible conclusions are that (i) the old treatment is better, (ii) there is no difference, or (iii) the new treatment is better. For our purposes, however, conclusions (i) and (ii) are functionally equivalent since either would lead us to retain the standard treatment. In this case, a one-tailed test, whose only goal is to test whether or not conclusion (iii) is true, might be an appropriate choice.

Note that a one-tailed test should be used only in a study in which, as in this example, an effect in the reverse direction is, for all intents and purposes, identical to "no effect." It is not appropriate to use a one-tailed test merely because one is able to specify the expected direction of the effect prior to running the study. In psychological research, for example, we typically expect that the new procedure will increase, rather than decrease, the cure rate. Nevertheless, a finding that it decreases the cure rate would be important, since it would demonstrate a possible flaw in the underlying theory. Even in the example cited, one would want to be certain that a profound effect in the reverse direction could safely be ignored—under a one-tailed test, it cannot be interpreted. In behavioral research, the use of a one-tailed test can be justified only rarely.

For a given effect size, sample size, and alpha, a one-tailed test is more powerful than a two-tailed test (a one-tailed test with alpha set at 0.05 has the same power as a two-tailed test with alpha set at 0.10). However, the number of tails should be set based on the substantive issue ("Will an effect in the reverse direction be meaningful?"). In general, it would not be appropriate to run a test as one-tailed rather than two-tailed as a means of increasing power. (Note also that power is higher for the one-tailed test only under the assumption that the observed effect falls in the expected direction. When the test is one-tailed, the power for an effect in the reverse direction is zero by definition).

3.14.3.4 Role of Sample Size in Power Analysis

For any given effect size and alpha, increasing the sample size will increase the power. As is true of effect size and alpha, sample size cannot be viewed in isolation but rather as one element in a complex balancing act. In some studies it might be important to detect even a small effect while maintaining high power. In this case it might be appropriate to enroll many thousands of patients (as was done in the "Physicians" study that found a relationship between aspirin use and cardiovascular events).

Typically, though, the number of available cases is limited. The researcher might need to find the largest *N* that can be enrolled, and work backwards from there to find an appropriate balance between alpha and beta. They may need to forgo the possibility of finding a small effect, and acknowledge that power will be adequate for a large effect only.

For studies that involve two groups, power is generally maximized when the subjects are divided evenly between the two groups. When the number of cases in the two groups is uneven the "effective *N*" for computing power falls much closer to the smaller sample size than the larger one.

There is one exception to the rule that an increase in sample size will always yield an increase in power. When we are working with exact formulas for discrete distributions, such as the binomial test for a single proportion or the Fisher exact test for a crosstabulation, it is possible that a modest increase in sample size will serve to lower power (Borenstein et al., 1997).

3.14.3.5 Computing Power in Power Analysis

Power is the fourth element in this closed system—for given effect size, alpha, and sample size, power is completely determined. A convention exists that power should be set at 80% but this convention has no clear *a priori* basis. The appropriate level of power should be decided on a case-by-case basis, taking into account the potential harm attendant on a type I error, the determination of a clinically important effect, the available sample size, as well as the importance of identifying a small, medium, or large effect.

While power is a function of three elements (effect size, sample size, and alpha), as a practical matter the effect size tends to dominate the calculation of power. Sample size plays a secondary role, and the impact of alpha is relatively modest. For example, with response rates of 30% vs. 50%, a sample size of 100 per group, and alpha (two-tailed) set at 0.05, power would be 83%. Consider, then, the impact of changes to these factors. If we elect to work with an effect size of 25 percentage points rather than 20 percentage points (i.e., 55% vs. 30% rather than 50% vs. 30%) power would be increased from 83% to 95%. To achieve the same 12-point increase in power by manipulating the sample size we would have to increase the sample size from the initial value of 100 per group to 160 per group. To achieve the same increase in power by selecting a more liberal value for alpha we would need to move alpha from 0.05 to 0.20.

Because the effect size plays such an important role in the computation of power, it is imperative for the researcher to use an appropriate effect size in the computations. If we use an effect size that is too large, then the study will not have adequate power to detect a more modest effect. If we use an effect size that is too low, then we might increase the sample size in an effort to reach acceptable levels of power, thus inappropriately putting patients at risk. Rather, the effect size used in the power analysis should be selected carefully, based on the kinds of substantive issues outlined earlier.

3.14.3.6 The Null Hypothesis vs. the Nil Hypothesis

Power analysis focuses on the study's potential for rejecting the null hypothesis. In most cases the null hypothesis is the null hypothesis of no effect, or the "nil" hypothesis. In some studies, however, the researcher might want to test another null hypothesis. For example, rather than testing the null hypothesis that a correlation coefficient is zero, a researcher might want to test the null hypothesis than the correlation is 0.80 (i.e., to demonstrate that the correlation exceeds this value). Intuitively, it is easier to show that an observed correlation exceeds zero than to show that it exceeds 0.80. In the latter case the effect size is smaller and a substantially larger sample would be required to ensure adequate power.

3.14.3.7 Retrospective Power Analysis

One occasionally sees a retrospective power analysis of the following form. A researcher completes a study, and reports that the effect size in the study was, for example, a standardized mean difference of $d=0.2$. The researcher then goes on to report that, based on this effect size, the study actually had power of only, for example, 40%. However well intentioned, this type of retrospective power analysis is generally misguided for several reasons. First, as noted earlier, the role of effect size in a power analysis is not "The effect size is $d=0.4$ and therefore power is 80%" but rather "If the effect size is $d=0.4$, then power would be 80%." The effect size $d=0.4$ is supposed to represent the smallest effect that would be important to detect. As such, it is not affected by evidence that the actual size of the effect might be larger or smaller than this value. Second, even if one wanted to base power on the "true" effect, the fact remains that the value observed in any single study is not likely to be the true effect. Indeed, if we had confidence that observed effect size was the true effect we would have no need to run another study to pinpoint the effect size, much less to test the hypothesis that it was zero.

While this application of a retrospective power analysis is inappropriate, there are two related applications where it may be useful. One is the use of study data to identify a base rate.

Assume, for example, that our goal is to reduce by 20% the proportion of patients having a panic attack within two days of treatment. Initially, we assume that the base rate for these attacks is 30%, compute power for a difference of 30% vs. 24% (corresponding to a 20% decrease), and set the sample size on this basis. It emerges in the study that the base rate is 20%, which means that we should have computed power for a difference of 20% vs. 16% (corresponding also to a 20% decrease). In this case, one could argue that the original power calculations were based on incorrect assumptions, and that for the *a priori* effect size the study was underpowered. Similarly, if the effect size was computed as a mean difference in raw units (such as SAT [Scholastic Achievement Test] scores) but we underestimated the standard deviation of the scores, one could argue that our initial computations had been in error and that power for the desired effect was too low. A second logical application along these lines is to use the study data to obtain a more informed estimate of the likely effect size by computing the confidence intervals based on the sample. This information could prove useful in the design of a subsequent study.

Retrospective power analyses are usually reported subsequent to a study that failed to yield a significant effect. Occasionally, though, researchers who have obtained a significant result may discover that their study had been under-powered and then wonder if the study results are still valid. Of course, this is a nonissue. Power tells us the likelihood is that the study will yield a significant effect and is used for purposes of planning. If the study is completed, then we know the outcome—either the effect was significant, or it was not. To worry in retrospect that the chances of success were small is akin to the parent whose teenager has taken the car for a ride during a bad rain but returned home safely. There might have been reason for worry while the teenager was still out (and the parent might want to be more careful the next time) but it makes no sense to worry about the outcome of this particular trip after the fact.

3.14.3.8 Ethical Issues in Power Analysis

Some studies involve putting patients at risk. At one extreme, the risk might involve a loss of time spent completing a questionnaire. At the other extreme, the risk might involve the use of an ineffective treatment for a potentially fatal disease. While an extensive discussion of research ethics is outside the scope of this chapter, it must be emphasized that ethical issues should play a central role in power analysis. If a study to test a new drug will have adequate power with a sample of 100 patients, then it would be inappropriate to use a sample of 200 patients since the second 100 are being put at risk unnecessarily. At the same time, if the study requires 200 patients to yield adequate power, it would be inappropriate to use only 100. These 100 patients consent to take part in the study on the assumption that the study is likely to yield useful information. If the study is underpowered, then the 100 patients will have been put at risk for no reason.

Of course, the actual decision-making process is complex. One can argue about whether "adequate" power for the study is 80%, or 90%, or 99%. One can argue about whether power should be set based on an improvement of 10 points, or 20 points, or 30 points. One can argue about the appropriate balance between alpha and beta. The point being made here is that these kinds of issues need to be addressed explicitly as part of the decision making process.

3.14.3.9 Power Analysis in Perspective

To this point we have focused on the details of a power analysis, but it is important also that the entire procedure be seen in an appropriate context. The use of a power analysis in study planning is appropriate only when the study goal is to test the null hypothesis. By contrast, if the study goal is to estimate the magnitude of a treatment effect, then statistical power has no bearing on sample size. Later in this chapter it is argued that most studies should focus on effect size estimation rather than power analysis, and so this becomes a critical point.

More generally, before performing a power analysis or any other procedure to set sample size, it behooves the researcher to ensure that the study should be conducted at all. Chalmers and co-workers have shown that many studies have put patients at risk in attempts to test treatments when, in fact, the data required to answer the question already existed from prior studies. In one famous example (Lau et al., 1992), a series of 33 randomized trials were carried out between 1959 and 1988 to assess the impact of intravenous (iv) streptokinase in preventing mortality subsequent to a myocardial infarction. In fact, the life-saving power of these drugs could have been proven as early as 1973, if the data available at that time had been subjected to a meta-analysis. At that time, a total of eight studies had been completed using a total of 2432 patients. The p-value for a test of the nil was < 0.01 and the effect size (odds ratio) 0.74 with a 95% confidence interval of

0.59–0.92. Subsequent to 1973, researchers ran an additional 25 studies which employed a total of 34 542 additional patients, with approximately half of these assigned to placebo and denied the potential benfits of the treatment. In fairness, it must be noted that meta-analysis was not widely accepted in 1973, and even if the researchers had access to meta-analytic methods, results based on a these procedures might not have been accepted by the medical community. Our intention is not to argue that this specific set of studies was not needed, but to make the point that the study must hold the potential to provide useful information and that power analysis is only one element in this process.

3.14.3.10 Some Real World Issues in Power Analysis

In some ways, the funding process and other constraints ensure that studies will continue to be run with low power. Feinstein (1975) may have identified one part of the problem with his straightforward account of how studies are designed in real life. The statistician (i) computes the maximum number of patients for which funding can be obtained, (ii) finds the effect size required to yield power of 80%, given the sample size, and (iii) develops a rationale to present to the finding agency to show that the effect size is the smallest effect size that would be clinically important to detect. The process identified by Feinstein leads to grant applicants asserting that a clinically important effect would be one that improves the response rate by precisely "22 percentage points."

In fact, the thrust of this approach is not necessarily inappropriate. The selection of an effect size should take into account any number of factors, and it might be appropriate to allocate resources to detect a large effect but not a small one. However, the grant application would be more credible if the applicant acknowledged that the effect size was set in this way, rather than arguing that the smallest effect of clinical importance would be a rate difference of precisely 22 percentage points.

3.14.3.11 Computer Programs for Power Analysis

Power is defined as the proportion of samples that will yield a statistically significant effect, given a specific set of assumptions. The computation of this value is a two-step process. First, we compute the effect size required to yield a significant effect, for the given alpha and sample size. Second, we compute the proportion of samples that will yield an effect this large (or larger), given the effect size in the population.

As a practical matter, computation of power is performed by means of computer programs designed for this purpose. The example that follows is taken from *Power and Precision*, a program developed by Borenstein et al. (1997). The example is for a study in which patients will be assigned at random to either a new treatment or the standard treatment, and we will compare the proportion responding in the two groups.

Computation of power proceeds as follows (Figure 3):

(i) Optionally, enter names for the two groups: "New treatment" and "Standard treatment."

(ii) Enter the proportion responding in either group: 40% for the standard group and 60% for the new treatment.

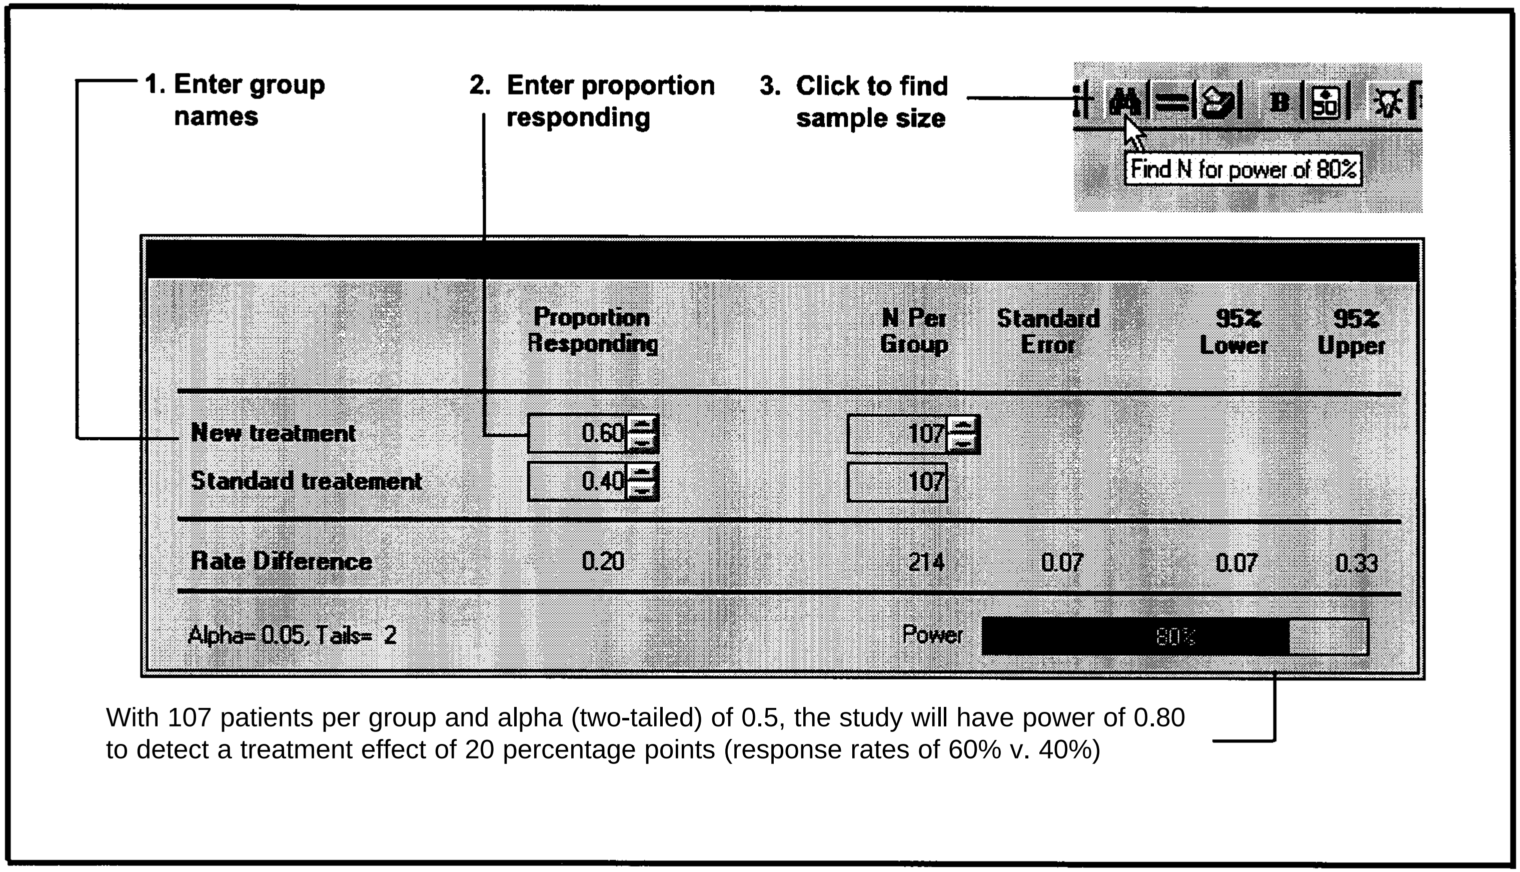
(iii) Click "Find N." The program shows that a sample of 107 per group will yield power of 80%.

(iv) At this point the researcher may elect to vary the study parameters, for example, to modify the effect size or sample size and see the impact on power. This may be done interactively. Alternatively, the program will automatically generate a table and graph that allows the researcher to simultaneously take account of several factors.

One possible graph is shown in Figure 4. The three lines in the graph represent treatment effects of 25 points, 20 points, and 15 points (specifically, response rates of 65% vs. 40%, 60% vs. 40%, and 55% vs. 40% for the new treatment vs. the standard treatments). The sample size required to yield power of 80% is 70 patients per group for the largest effect, 107 per group for the second effect, and 186 per group for the third.

In this example, taking account of substantive issues and available resources, we decide that we will base the study on the center line. In other words, we decide that a 20-point improvement in response rates is important enough to justify a trial with 107 patients per group. By following the trajectory of the center line we see that 139 patients per group would yield power of 90% for this effect, but decide that we cannot commit the additional resources. By comparing the position of the three lines at "107 per group" we note that if the treatment effect is actually 25 points (65% vs. 40%) rather than 20 points, then the study's power is actually 95% rather than 80%. If the true effect is actually 15 points (55% vs. 40%) then power is actually 54%.

The program will also generate a text report of the computation which serves as an educational tool and may also be copied into



1. Enter group names

2. Enter proportion responding

3. Click to find sample size

	Proportion Responding	N Per Group	Standard Error	95% Lower	95% Upper
New treatment	0.60	107			
Standard treatement	0.40	107			
Rate Difference	0.20	214	0.07	0.07	0.33

Alpha= 0.05, Tails= 2

Power 80%

With 107 patients per group and alpha (two-tailed) of 0.5, the study will have power of 0.80 to detect a treatment effect of 20 percentage points (response rates of 60% v. 40%)

Figure 3 Screen from *Power and Precision* showing computation of power. The researcher enters an effect size (response rates of 60% vs. 40%), alpha (0.05, two-tailed) and clicks "Find N" on the toolbar. The program shows that a sample size of 107 per group will yield a power of 80%. The researcher may modify any of the study parameters, and the program will update power automatically in response.

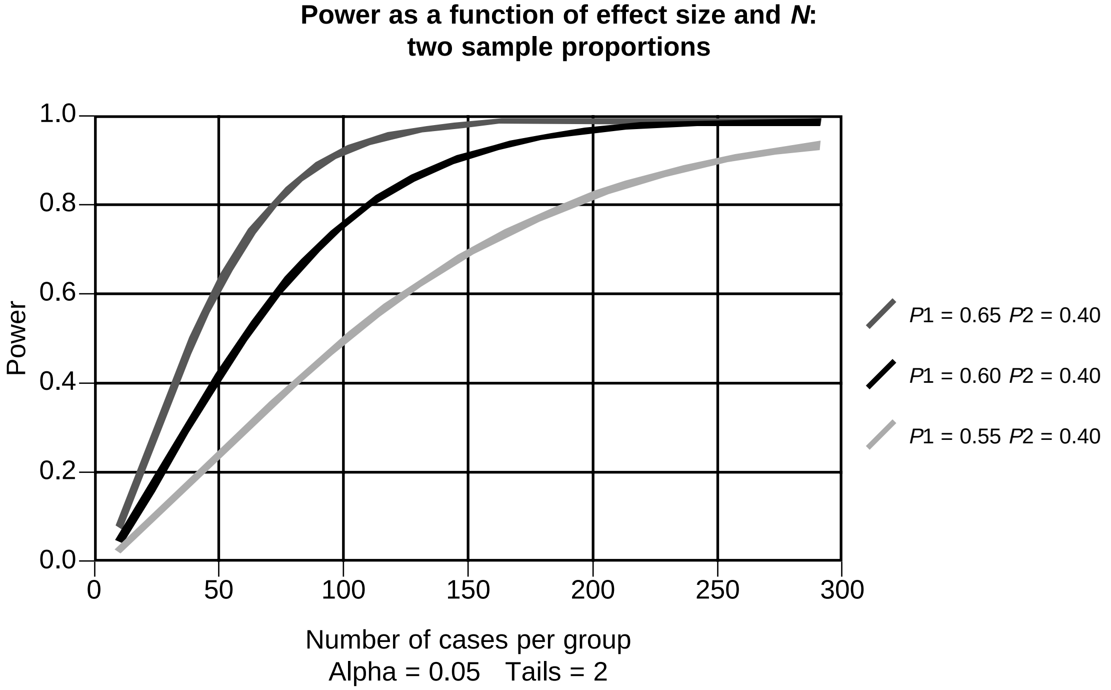


Figure 4 Power as a function of effect size and sample size. This graph, which is an extension of Figure 3, allows the researcher to take account of multiple factors simultaneously while planning the study. We can design the study to detect the largest effect (top line) which would require only about 70 cases per group but would result in low power to detect the more modest effects. We can design the study to detect the middle effect, which would require 107 cases per group but would result in low power to detect the smallest effect. To ensure power for the smallest effect (with the least potential benefit) we would need to enroll some 180 cases per group.

a word-processing program. In this example the text of the report reads (in part) as follows: "One goal of the proposed study is to test the null hypothesis that the proportion responding is identical in the two populations. The criterion for significance (alpha) has been set at 0.05. The test is two-tailed, which means that an effect in either direction will be interpreted. With the proposed sample size of 107 and 107 for the two groups, the study will have power of 80.1% to yield a statistically significant result. This computation assumes that the difference in proportions is 0.20 (specifically, 0.60 vs. 0.40). This effect was selected as the smallest effect that would be important to detect, in the sense that any smaller effect would not be of clinical or substantive significance. It is also assumed that this effect size is reasonable, in the sense that an effect of this magnitude could be anticipated in this field of research."

The software available for power analysis is constantly changing but up-to-date information is available on the Internet. Information on the program used in this example is available at http://www.PowerAndPrecision.com. Thomas and Krebbs (1997) maintain a site with links to any number of programs for power analysis at http://www.Interchg.ubc.ca/cacb/power.

3.14.4 PROBLEMS WITH THE SIGNIFICANCE TEST

To this point we have highlighted the key features of significance testing and power analysis. The vast majority of statistical analyses in psychological research take the form of significance tests and an understanding of the process is essential to an understanding of the research literature.

However, this was intended primarily as an introduction. The thesis of this chapter is that while the significance test is ubiquitous in the literature of psychological and medical research, its use in these fields is inappropriate for a number of reasons. In this section we will make the following points:

(i) The significance test addresses the wrong question. Researchers are concerned with clinical significance (i.e., the magnitude of the treatment effect), but significance tests address statistical significance (whether or not the effect is zero).

(ii) The question that is addressed by significance tests (whether or not the null hypothesis is true) is inappropriate not only because it is tangential to clinical significance but also because it is almost always false in psychological research.

Additional problems derive from the fact that significance tests lend themselves to mistakes of interpretation. In particular:

(i) A significant p-value is assumed to reflect a clinically important effect, and the level of significance is assumed to reflect the magnitude of the effect. In fact, though, the p-value incorporates information about the size of the sample as well as the size of the effect. Therefore, the use of the p-value for this purpose results in confusion and errors of interpretation.

(ii) Historically, a majority of studies have been run with low power, which means that even moderate or large treatment effects may go undetected. Additionally, the absence of significance is often interpreted, inappropriately, as evidence that the treatment effect is zero. The combination of these two types of error has seriously impeded research in psychology.

3.14.4.1 Significance Tests Address the Wrong Question

The key problem with significance testing is that it addresses the wrong question. The question that researchers want to ask is "How large is the treatment effect?" By contrast, the question actually addressed by the significance test is "Can we conclude that the treatment effect is not zero?"

Researchers typically assume that reports of "significance" or "nonsignificance" refer to clinical significance. This assumption follows from the fact that clinical significance is the question of interest, and also from the fact that "significance" refers to substantive (or clinical) significance in common parlance. Nevertheless, this assumption is incorrect. A significant p-value tells us only that the treatment (probably) increases the response rate by some amount. It does not provide information about the size of the effect.

The clinician, of course, needs information about the magnitude of the treatment effect—Does the treatment increase the likelihood of response by five percentage points, or 10 points, or 50 points?—since this is the kind of information required to balance the treatment's potential benefits against the costs and potential side effects. It is also the kind of information required to allow for an informed choice between the treatment in question and other possible treatments. The only information that the significance test can provide—that the treatment effect exceeds zero—is at best of tangential interest.

The same point being made here about implications for clinical practice applies also to the development of psychological theory. For example, Tukey (1969) points out that if the nature of elasticity had been defined as "when you pull it, it gets longer" the science of elasticity would have progressed very slowly. In psychological research as well, we need to address the size of the effect in order for theory to develop, and this is not addressed by the significance test.

3.14.4.2 The Null Hypothesis is not a Viable Hypothesis

There is a second problem with the use of the null hypothesis in psychological research. In addition to being irrelevant, it is also not a viable hypothesis, in the sense that it is known to be false in the overwhelming majority of psychological research.

For example, consider studies that compare the impact of two treatments. Hunter (1997) points to a survey conducted by Lipsey and Wilson (1993) which reviewed 302 meta-analyses of treatment studies in psychology and education. The average number of studies in each meta-analysis is 60, and the total number of studies included is 18 120. The treatment effect was zero (the null hypothesis was true) in less than 1% of the domains studied. Similarly, studies that look at the relationship between behaviors or traits are designed to test the null hypothesis that the correlation between traits is zero. In fact, though, it would be difficult to name two human characteristics whose correlation with each other is 0.0000000. In this kind of study the null hypothesis is always false.

The typical retort to the argument that the null is always false is that we do not intend to test whether or not the response rates are identical—rather, we intend to test whether or not they differ by some important amount. But this is exactly the problem. What we care about is whether or not the difference is clinically important, but what we are testing is whether or not the difference is exactly zero (Cohen, 1990).

This fact, followed to its logical conclusion, leads to an interesting paradox. Given that the effect is not zero, and since the p-value is a function of both effect size and sample size, it follows that with a large enough sample size, any effect will meet the criterion for significance. One can extend this argument in several ways:

(i) With a large enough sample size we know the study will yield a significant effect, so there is no need to run the study (Cohen, 1994).

(ii) With a large enough sample size we know the study will yield a significant effect, so if our result is not significant, then by definition we are committing a type II error (Schmidt, 1992).

(iii) With a large enough sample size the study will yield a significant effect, so what we are really testing is not whether the effect is large, but whether or not we have run enough subjects. Thompson (1992) suggests that instead of testing for significance we can assess how tired the researchers are. If they are tired, then we probably ran a lot of subjects and have a "significant" effect. If they are very tired, then we probably ran even more subjects and have a "very significant" effect.

There are exceptions to this point, which are discussed later, but these are rarely encountered in psychological research.

3.14.4.3 The Gratuitous Use of Significance Tests

Even those who argue that significance tests can serve an important role in psychological research recognize that the tests are almost invariably abused. Abelson (1997a) wrote a chapter in which he argues that the null hypothesis should not be banned, but includes a section entitled "The Null Hypothesis: Merely Misused, or Really Idiotic?" He uses the term "gratuitous" to describe the ritualistic application of significance tests to all kinds of data where the test could not possibly provide any useful information.

Indeed, significance tests are sometimes applied in ways that defy common sense. Abelson (1997a) cites the example of a researcher who divided a cohort of subjects at the group median into "low" and "high" groups and then performed a significance test to find out whether or not the groups were, in fact, different. In doing so the researcher missed the point that we use significance tests to make inferences about whether or not the groups differ in some systematic way, but in this case we know that they differ systematically because we created them that way. Simply put, one is high and one is low. In fact, this is the archetypical case of the situation cited earlier, where the groups clearly differ, and the only thing being tested is whether or not we have a large enough sample. What if the test had failed to yield a significant effect? Would the researcher have concluded that he had assigned persons to the two groups at random?

Cohen (1994) cites the case of a researcher who wanted to test the hypothesis that a particular ailment would never exist in a specific population. He tested 30 patients and found the ailment in only one. He wanted to know whether or not this (one case in 30) was "significant." In doing so, he missed the point that the theory required that there be no cases in the population, and if he found any then the theory was clearly false.

Papers are often seen in which persons report significance tests for reliability coefficients, in effect making the point that the scale's reliability is not zero. To show that the test has reliability better than zero is hardly reassuring to potential users of the test. Surely, the relevant question is whether or not the reliability exceeds 0.70 or 0.80. Abelson (1997b) suggests that "... declaring a reliability coefficient to be nonzero constitutes the ultimate in stupefyingly vacuous information" (p. 13).

Cohen (1994) traces the history of harangues against null hypothesis significance testing (NHST) and some of his quotes are reproduced here. Rozeboom (1960) wrote "The statistical folkways of a more primitive past continue to dominate the local scene" (p. 417). Bakan (1966), writing that "a great deal of mischief has been associated [with the significance test]" noted that the idea was hardly original with him and that "to say it 'out loud' is ... to assume the role of the child who pointed out that the emperor was really outfitted in his underwear" (p. 423). Meehl (1967) likened NHST to "a potent but sterile intellectual rake who leaves in his merry path a long train of ravished maidens but no viable scientific offspring." Rothstein (personal communication) noted that "... researchers [using NHST] often pose the wrong question and then proceed to answer that question incorrectly."

Cohen (1994) goes on to say that " ... we, as teachers, consultants, authors, and otherwise perpetrators of quantitative methods, are responsible for the ritualization of null hypothesis significance testing ... to the point of meaninglessness and beyond ... NHST has not only failed to support the advance of psychology as a science but also has seriously impeded it" (p. 997) (see also Cohen, 1990).

Rothman (1986b) writes "Testing for statistical significance today continues not on its own merits as a methodological tool but on the momentum of tradition. Rather than serving as a thinker's tool, it has become for some a clumsy substitute for thought, subverting what should be a contemplative exercise into an algorithm prone to error" (p. 447).

Additional citations on this topic include Abelson (1995, 1997a, 1997b); Borenstein (1994b); Carver (1978); Dar (1987); Estes (1997); Fisher (1959); Gonzalez (1994); Hagen (1997); Harlow, Mulaik, and Steiger (1997); Harris (1997a, 1997b); Hunter (1997); Loftus (1991); Lykken (1968); Meehl (1967, 1978, 1990); Murphy (1990); Neyman and Pearson (1932a, 1932b); Oakes (1986); Peto and Doll (1977); Scarr (1997); Schmidt (1992, 1996); Schmidt and Hunter (1996); Shaver (1993), and Shrout (1997).

3.14.4.4 *p*-Values: Responding with a Misdirected Answer

To this point we have shown that significance tests address a question that is at best tangential to the question of interest and at often entirely irrelevant. The use of significance tests carries with it an additional problem: Significance tests produce *p*-values that lend themselves to mistakes of interpretation.

The "*p*-value" highlighted by the significance test is a function of two elements—the size of the effect, and the precision of the estimate. When we consider the logic of the significance test, that is, to determine whether or not the population effect is zero, we can appreciate the simple elegance of the *p*-value. Either a large effect, or a large sample (yielding a precise estimate of the effect), or some appropriate combination of the two, provides evidence that the effect is not zero. By the same logic, however, it would not be appropriate to press the *p*-value into service as an indicator of effect size. Since the *p*-value incorporates information about both the size of the effect and the size of the sample, it does not allow us to distinguish between the two.

3.14.4.4.1 Misinterpreting the significant p*-value*

Statistical significance is often assumed to reflect substantive significance. Almost invariably, the first question asked by the reader, and the first point made by the researcher, is that the results were "significant." This is the point highlighted at meetings, in abstracts, and in the results section of publications. Often, the discussion of effect does not proceed beyond the question of significance at all. Even when it does, the issue of significance, that is, statistical significance, is emphasized over clinical significance or effect size. In fact, though, the only information imparted by a statistically significant *p*-value is that the true effect is (probably) not nil. A significant *p*-value could reflect a clinically meaningful effect. It could also reflect a clinically trivial effect that had been found in a large sample (because of the large sample the effect size is reported precisely, and though small is known to be non-nil).

Cohen (1965) writes "Again and again, the results section of an article describing an effect as significant or highly significant is followed by a discussion section which (usually implicitly) proceeds to treat the effect as if it had been found to be large or very large" (p. 102). The same point has been documented repeatedly in the field of psychology and medicine (Feinstein, 1975, 1976, 1977; Friedman & Phillips, 1981; Mainland, 1982; Nelson, Rosenthal, & Rosnow, 1986; Rothman, 1986b; Tversky & Kahneman, 1971; Wonnacott, 1985).

A review of a manuscript is recalled that purported to show a substantial advantage for a novel antipsychotic drug. The basis for this claim was a difference between treatment groups on a critical variable, with $p < 0.001$. As it happens, the sample size was of the order of 2000 patients, and a *p*-value <0.001 could reflect a difference that was so small as to be trivial. In fact, some of the baseline differences between the groups (which had, appropriately, been dismissed as negligible in size) were larger (and more significant!) than the post-treatment differences being submitted as evidence of the drug effect.

It gets worse. If the confusion of statistical significance with clinical significance is a problem in the interpretation of single studies, the situation is even worse when researchers use *p*-values to compare the results in different studies. This type of comparison is common when we want to know if the treatment is more effective in men than it is for women, or if one treatment is more effective than another.

Since the *p*-value incorporates information about both the sample size and effect size, a *p*-value of 0.05 could represent response rates in two groups of 50% vs. 70% (a 20-point effect) with a sample size of 50 cases per group. It could also represent response rates of 50% vs. 90% (a 40-point effect) with a sample size of 10 cases per group. In the second case the effect size is substantially larger than it is in the first case, but this fact is lost in the *p*-values, which are identical. Similarly, a *p*-value of 0.01 could represent response rates of 40% vs. 65% (25 points) with 50 cases per group, or 40% vs. 95% (55 points) with 10 cases per group. Again, the difference in effect sizes is not evident from the *p*-value.

In fact, Tversky and Kahneman (1971) found that students presented with information about *p*-values and sample sizes tend to make exactly the wrong conclusions about the effect size. Students were presented with two studies where the *p*-value was 0.05, and told that the sample size was 10 per group in one and 50 per group in the other. Invariably, students assumed that the effect size in the second case was more impressive, while exactly the reverse is true (see also Berkson, 1938, 1942; Friedman & Phillips, 1981; Rosenthal & Gaito, 1963, 1964; Rozeboom, 1960).

The possibilities for mistakes expand when we consider the possibility of comparing results between studies when both the *p*-value and the sample size differ. If one study yielded a *p*-value of 0.05 and another yielded a *p*-value of 0.01, then in the absence of any additional information a reader might assume that the effect size was stronger in the latter case. In fact, though, if the first study ($p = 0.05$) used a sample of 10 per group and the second ($p = 0.01$) used 50 per group, then the effect size would have been substantially larger in the study with the modest p-value (a 40-point effect as compared with a 25-point effect).

3.14.4.4.2 Misinterpreting the nonsignificant p*-value*

The complement to misinterpreting the significant p-value is to misinterpret the nonsignificant p-value. The only information imparted by a nonsignificant p-value is that we have failed to reject the null. Assume, for example, that refractory schizophrenic patients currently in relapse are assigned to be treated either with clozapine or with haldol. In this hypothetical example we find that the proportion meeting a remission criterion within six weeks is not significantly different in the two groups. The nonsignificant p-value could reflect a finding in a large sample that the proportion remitting was virtually identical in the two groups (the large sample ensuring to a high degree of certainty that the same would hold true in the population). Or, it could reflect a finding in a small sample that the remission rate was twice as high (or more) for the patients treated with clozapine (the finding failing to prove significant in part because of the low sample size). The first scenario would justify a conclusion that clozapine does not substantively increase the likelihood of remission and the second scenario would not justify this conclusion. However, researchers and readers almost invariably fail to make this distinction, and routinely interpret the absence of significance to mean that an effect does not exist. A related problem is the fact that many studies in psychological research suffer from low statistical power. In this section we will make four points.

(i) Power for research in psychology is abysmally low;

(ii) Rule (i) appears to be impervious to change;

(iii) The absence of significance should be interpreted as "more information is required" but is interpreted in error as meaning "no effect exists"; and

(iv) Rule (iii) appears to be impervious to change.

While Cohen has often made the point that he discovered, rather than invented, power analysis, the fact is that Cohen's papers over a series of decades have played a key part in making researchers aware of the power issue, and providing them with the mechanisms for computing power. At present, Cohen's papers and texts (Cohen, 1962, 1965, 1969, 1977, 1988, 1990, 1994) also serve as a kind of historical map that traces the role of power analysis since the 1960s.

Cohen (1962) surveyed papers published in the *Journal of Abnormal and Social Psychology* in 1960. Mean power to detect a small, medium, or large effect, respectively, was 0.18, 0.48, and 0.83. (Definitions of small, medium, and large were developed by Cohen with reference to the effect sizes typically found in social science research; the definitions were modified slightly subsequent to the 1962 paper.) The implications of this were spelled out clearly in the paper. At a minimum, a great deal of time and effort is being wasted on studies that have little chance of meeting their goals. Worse, when the studies with "negative" results are published, readers tend to interpret the absence of statistical significance as evidence that the treatment has been proven ineffective.

What was the response to this paper? Woody Allen has spoken of the time that he was kidnapped as a child. It took his father a while to catch on ("He had bad reading habits—he started reading the ransom note, but in the middle he fell asleep") but eventually he "sprang into action and rented out my room." In that vein, it took the scientific community a while to appreciate the implications of Cohen's paper but eventually it sprang into action also. First one, then another researcher found that what Cohen had done for the field of psychology could be done equally as well for any field of research, and in the years that followed a kind of cottage industry developed of papers that documented the fact of low power in any number of journals in the area of behavioral research. Many of these are cited in Sedlmeier and Gigerenzer (1989) and Rossi (1990). Similar papers were published to document the same problem in the field of medicine (Borenstein, 1994b; Hartung, Cottrell & Giffen, 1983; Phillips, Scott, & Blasczcynski, 1983; Reed & Slaichert, 1981; Reynolds, 1980) and psychiatry (Kane & Borenstein, 1985).

One oft-cited paper by Frelman, Chalmers, Smith and Kuebler (1978) surveyed reports of controlled clinical trials that had been published in a number of medical journals (primarily the *Lancet*, the *New England Journal of Medicine*, and the *Journal of the American Medical Association* during the period 1960–1977), and selected 71 that had reported negative results. The authors found that if the true drug effect had been on the order of 50% (e.g., a mortality rate of 30% for placebo vs. 15% for drug), median power would have been 60%. In other words, even if the drug cut the mortality rate in half there was still a 40% probability that the study would have failed to obtain a significant result.

How does the story end? In Woody Allen's tale the FBI surrounded the kidnappers. They wanted to "toss in the tear gas," but they had no tear gas so instead they put on the death scene from Camille. The kidnappers were overcome. The FBI and the kidnappers bargained with each other and eventually reached an agreement that the kidnappers would "throw out their guns and keep the kid."

The power analysis story has a similar ending. In keeping with the general move away from isolated studies and toward meta-analysis, papers that document low power in specific journals are now being replaced by meta-analysis of these papers. Now, researchers have been able to document the fact that low power exists not only in specific journals, but also in every field of research.

Sedlmeier and Gigerenzer (1989) published a paper entitled "Do studies of statistical power have an effect on the power of statistical studies?" They found that in the 25 years since Cohen's initial survey power had not changed in any substantive way. Specifically, they reported that in the 1984 volume of the *Journal of Abnormal Psychology*, mean power to detect small, medium, and large effects was 0.21, 0.50, and 0.84, which are essentially similar to the values reported by Cohen for the 1960 volume (in 1960, for the *Journal of Abnormal and Social Psychology*). Similarly, Rossi (1990) reviewed papers published in 1982 in the *Journals of Abnormal Psychology, Consulting and Clinical Psychology*, and *Personality and Social Psychology*. Mean power to detect small, medium, and large effects, respectively, was 0.17, 0.57, and 0.83. In fact, since papers with higher power are more likely to yield significant results and be published, the mean power reported by these surveys is almost certainly higher than the mean power for all studies in the field.

Given that the fact of low power is well documented, one would hope that researchers would adapt their thinking to accommodate to this state of affairs. In fact, though, the mistake of interpreting nonsignificant results as implying the absence of an effect runs through the psychological and medical literature. One could say that it practically gallops.

Cohen (1990) relates the story of a doctoral candidate who completed a study with 20 cases per group, and power of 0.33 to detect a medium sized effect. As Cohen recalls "He ended up with non-significant results—with which he proceeded to demolish an important branch of psychoanalytic theory" (p. 1304).

Earlier, the paper by Freiman et al. (1978) was cited, showing that power for papers published in some of the most prestigious medical journals was clearly at unacceptable levels. The authors went on to make a second point: Despite the fact that power was terribly low, in most cases the absence of significance was interpreted as meaning that the drug was not effective. The authors wrote: "The conclusion is inescapable that many of the therapies discarded as ineffective after inconclusive 'negative' trials may still have a clinically meaningful effect" (p. 694). In fact, it is possible (or likely) that some of the therapies discarded on this basis might well have had very substantial therapeutic effects.

In fact, Sedlmeier and Gigerenzer reported that power had actually dropped slightly over the 25 years subsequent to Cohen's initial survey. The magnitude of the drop is of little consequence, but the reason for the drop is interesting—researchers in 1990 were more likely to be making adjustments to alpha when running multiple tests (e.g., using alpha of 0.025 rather than 0.05) to ensure that the type I error rate was kept at 0.05. Schmidt (1996) points to the irony that researchers were protecting themselves against an error that could not occur (since the null hypothesis was false) while oblivious to the type II error rate, which exceeds 50%.

As was the case for misinterpretation of significant results, the misinterpretation of nonsignificant results becomes even more complicated when researchers try to compare results across studies. One would hope that the error of interpretation would be obvious when there are a series of studies, with some yielding a significant effect and others failing to do so. In some such series the effect size is remarkably consistent from one study to the next—the studies with a large sample size met the criteria for significance and those with a smaller sample size did not. Even in these cases, however, there is usually a perception that "the studies yield conflicting results."

Even in 1998 a cardiologist remarked that thrombiolytics are incredibly effective in reducing mortality for patients suffering a myocardial infarction, and that he sees clearly that they save lives, but that the studies of effect "flip back and forth." In fact, thrombiolytics represent the textbook case (literally) cited earlier (Lau et al., 1992), where the treatment effect is consistent from one study to the next, and the presence or absence of statistical significance varies with sample size.

Even worse, when the significant study was performed in one type of sample and the nonsignificant study was performed in another type of sample, researchers sometimes try to interpret this difference as meaning that the effect exists in one population only (e.g., males but not females). Abelson (1997a) notes that if a treatment effect yields a p-value of 0.07 for wombats and 0.05 for dingbats we are likely to see a discussion explaining why the treatment is effective only in the latter group—completely missing the point that the treatment effect may have been virtually identical in the two. The treatment effect may have even been larger in the nonsignificant group, if the sample size was smaller.
